Matsumoto, Michinaga, Hirokazu Yokoyama, Hidekazu Suzuki, Haruko Shiraiishi-Yokoyama, and Toshifumi Hib. Retinoic acid formation from retinol in the human gastric mucosa: role of class IV alcohol dehydrogenase and its relevance to morphological changes. Am J Physiol Gastrointest Liver Physiol 289: G429–G433, 2005. First published April 28, 2005; doi:10.1152/ajpgi.00502.2004.—Alcohol dehydrogenase (ADH) participates in the formation of retinoic acid from retinol in various organs including the gastric mucosa. However, its clinical significance still remains to be clarified. In this study, we identified the ADH isoforms responsible for the retinoic acid formation among various ADH isoforms and examined associations among the ADH activities, the retinoic acid formation level, and morphological changes in the human gastric mucosa. Human gastric samples were endoscopically obtained from 67 male subjects. Morphological changes were assessed by the Sydney system and activities of class I, III, and IV ADH isoforms were determined in each specimen. In 26 cases, levels of all-trans retinoic acid (ATRA) formation from all-trans retinol were examined. Among activities of the three ADH isoforms, class IV ADH activity was solely associated with the ATRA formation level. This association was found even when subjects’ age and ADH activity was solely associated with the ATRA formation level. The results of this study showed that retinoic acid is formed from retinol in the human gastric mucosa: role of class IV alcohol dehydrogenase and its relevance to morphological changes.

MATERIALS AND METHODS

Materials and human gastric mucosa samples. Most chemicals and supplies were purchased from Sigma-Aldrich (St. Louis, MO). All studies involved in this report were approved by the Ethics Committee of School of Medicine, Keio University, based on the ethics guidelines of the 1975 Declaration of Helsinki. Male patients undergoing endoscopy examinations of upper digestive tracts for various reasons were asked by written consent form to provide extra tissues from the midcorpus region of the stomach for research purposes. Finally, samples were collected from 67 donors aged 50.3 ± 13.7 (mean ± SD) years who understood the aims of the study and agreed to donate samples. After sampling, half of each specimen was fixed in 10% formaldehyde for histological examination and the remaining tissue fraction was prepared as described in previous reports (17) just before the experiments. The amount of protein in each fraction was measured by Lowry’s method (16) using a kit. Among the 67 cases, extra samples were available in 26 cases and the formation of retinoic acid from retinol could be further examined in them.

Activity of classes I, III, and IV ADHs in the human gastric mucosa. Activities of the human gastric ADHs were assessed according to the methods previously reported (6, 17). Activities of class I and IV ADHs were measured by the reduction of their preferred substrates, namely acetaldehyde and m-nitrobenzaldehyde, respectively, in the presence of NADH. Briefly, 200 μg each of human gastric cytosolic protein was incubated at 37°C in 0.1 M sodium phosphate buffer (pH 7.5) containing 100 μM of NADH and 250 μM of acetaldehyde or 100 μM of m-nitrobenzaldehyde, with a total volume of 3 ml. Decrease in absorbance at 340 nm was measured for 5 min using a spectrophotometer (model MOPS-2000; Shimadzu, Tokyo, Japan). The activity of class III ADH was measured by the oxidation of its preferred substrate, formaldehyde, in the presence of GSH and NAD. Briefly, each sample was incubated at 25°C in 0.1 M sodium pyro-

phosphate buffer (pH 8.0) containing 1.2 mM of β-NAD, 1 mM of GSH, and 1 mM of formaldehyde (Wako Junyaku, Tokyo, Japan), with a total volume of 3 ml. Evaporating of substrates during the incubation was prevented by tightly covering each cuvette with Parafilm. A mixture without gastric sample was used as the blank of each spectrophotometrical ADH assay. Increase in absorbance at 340 nm was measured for 5 min using the spectrophotometer. Class I and IV ADH activities were expressed in nanomoles NAD reduction per minute per milligram protein and that of class III ADH was done in nanomoles NAD reduction per minute per milligram protein.

Formation of ATRA from all-trans retinol. The level of ATRA formation from all-trans retinol was assessed in 26 cases based on the HPLC methods established in our laboratory (19, 35). Fifty micrograms of each human gastric cytosolic fraction were incubated with 3 μg of all-trans retinol and 2 mM of β-NAD at 37°C for 20 min in 20 mM of HEPES buffer (pH 7.5) containing 150 mM of potassium chloride and 2 mM of d,L-DTT, in a total volume of 1.5 ml. After the reaction, 500 μl of ethanol, 500 μl of saturated ammonium sulfate, 2 ml of distilled water, and 4 ml of a solution containing n-hexane, acetic acid, and dichloromethane in a ratio of 80:9:1 were added to 500 μl of each reaction mixture and shaken for 10 min. Twenty micromoles of arotinoid ethylsulfone, kindly donated by Hoffmann-La Roche (Basel, Switzerland), were added to each sample as an internal standard. Samples were centrifuged at 2,700 g for 4 min, and the organic layer (upper layer) was collected using a glass pipette. The organic solvent was evaporated using nitrogen gas, and the extracts were resolved in 200 μl of n-hexane. Fifty microliters of the solution were used for HPLC quantification, by the method established by our laboratory (19). Areas under the curve for ATRA and arotinoid ethylsulfone used as an internal standard were calculated by a chromatointegrator. The ATRA level in each sample was quantified by using a working curve established in our laboratory, adjusting the level of the internal standard (19, 35). All procedures were performed under a safety light or in the dark to avoid photoisomerization of the retinoids (35).

Histological assessment. Three-micrometer-thin sections were prepared from the paraffin-embedded specimens and stained with hematoxylin and eosin. Specimens were examined under a light microscope by an expert in stomach pathology, and the degree of each parameter was ranked according to the Sydney system (25). Statuses of inflammation, atrophy, intestinal metaplasia, and neutrophil infiltration were evaluated using a graded scale: absent (grade 1), mild (grade 2), moderate (grade 3), and severe (grade 4). The presence of Helicobacter pylori infection in situ was also judged in each hematoxylin and eosin-stained specimen.

Statistical analysis. Values were described as means ± SD or SE. The difference between multiple groups was assessed by one-way ANOVA with Fisher’s exact test as a post hoc test. The correlations among multiple groups were assessed by multiple regression analysis. A P value of <0.05 was considered statistically significant.

Values are multiple regression analysis for levels of retinoic acid formation; n = 26 subjects. Multiple coefficient of determination (R²), 0.580; adjusted multiple coefficient of determination, 0.496; ADH, alcohol dehydrogenase; ATRA, all-trans retinoid.

RESULTS

The activities of class I, III, and IV ADHs were 16.1 ± 11.1 NADH oxidation⋅min⁻¹⋅mg protein⁻¹, 2.7 ± 1.7 NAD reduction⋅min⁻¹⋅mg protein⁻¹, and 9.4 ± 4.4 NADH oxidation⋅min⁻¹⋅mg protein⁻¹, respectively, in this population. Results of histological examinations in 67 gastric specimens according to the Sydney system (25) are summarized in Table 1.

Among the 67 subjects, ATRA formation levels from all-trans retinol in the human gastric mucosa were studied in 26 samples and the correlation between the ATRA formation level and activities of the three ADH forms was studied by multiple regression analysis. As shown in Table 2, the activity of class IV ADH was correlated with the ATRA formation (P = 0.0019), whereas those of class I (P = 0.2451) and III (P = 0.0730) ADHs were not. The association between class IV ADH activity and the retinoic acid formation level was further confirmed by multiple regression analysis in which subject age and in situ H. pylori infection status were adjusted (P = 0.0020; Table 3).

The relationships between three ADH activities and morphological changes in the gastric mucosa as judged by the Sydney system were then also examined by multiple regression analysis. As shown in Table 4, degrees of inflammation, intestinal metaplasia, and atrophy were inversely correlated with class IV ADH activities in the human gastric mucosa, but not with those of class I and III ADH activities. The inverse correlations between class IV ADH activity and the degrees of the three parameters of morphological changes were confirmed by multiple regression analysis in which subject age and in situ H. pylori infection status were adjusted (Table 5).

The associations between the morphological changes and the level of retinoic acid formation were then studied in the gastric specimens. As shown in Fig. 1, as degrees of inflammation (λ = 22.72, P = 0.0003, Fig. 1A), intestinal metaplasia (λ = 8.12, P = 0.0687, Fig. 1B), and atrophy (λ = 10.80, P = 0.0116, Fig. 1C) increased, the retinoic acid formation levels significantly decreased or showed a trend to decrease.

DISCUSSION

In the present study, a key enzyme for ATRA formation from retinol in the human gastric mucosa was identified. Furthermore, the relationships among ADH activities, potential for ATRA formation from all-trans retinol, and features of histological changes were examined in the human gastric mucosa. Recently, a gender difference in gastric ADH activities has been reported (1). Although the view seems to be still
equivocal (15, 17, 20, 23), male subjects were selectively studied at this time. In this study, each ADH isoform was spectrophotometrically evaluated using its preferred substrate (6). Although slight errors including that due to the evaporation of substrate and that due to types of blanks are inevitable in a spectrophotometrical assay, methods used in the present study are widely accepted (4, 6). In this study, a specimen without a gastric sample was used as a blank for each spectrophotometrical assay. Although other types of blanks including ones without substrate or without coenzyme could be applicable, we chose our method because of the limitation of sample availability.

Our previous findings that several ADH inhibitors hampered this NAD-dependent ATRA formation from retinol in the human gastric mucosa (36) suggested that some ADHs have a significant role in this process, at least in part. In the present study, we clarified which ADH form is responsible for this process among three ADH isoforms expressed in the human gastric mucosa. The present multiple regression analysis showed that only class IV ADH but not class I and III ADHs were associated with the ATRA formation level. This indicates that among ADH isoforms in the human gastric mucosa class IV ADH has a major role on the NAD-dependent ATRA formation. Compared with the $K_m$ values for retinol of three ADHs expressed in the human gastric mucosa, i.e., class I, class III, and class IV ADHs, the finding is reasonable (3, 11, 14). The association between the class IV ADH activity and the ATRA formation level was further confirmed even after adjusting subject age and status of $H. pylori$ infection in another multiple regression analysis. Although factors different from ADH, including ALDH activity and substrate concentration should also affect this process, we could not examine these points at this time because of the limitation of sample availability.

In the present study, the ATRA formation in the human gastric mucosa was studied in the protocol established in our laboratory (36). Because the concentration of all-trans retinol in the protocol (0.007 mM) was similar to the reported $K_m$ value for all-trans retinol of class IV ADH (0.008–0.0031 mM; Refs. 3, 11, and 14), it might not provide its $V_{max}$, i.e., the retinol oxidation rate measured here would be different from optimal one. Because all specimens were studied in the equal conditions, the comparison of the ATRA formation level in this study should be meaningful even if the enzyme activity is not maximal. However, we must be careful for the interpretation of the present findings.

Although the associations between the ADH activities and histological changes in the gastric mucosa have already been demonstrated (8, 20, 27), the advantages of the present study were that 1) activities of three ADH isoforms were specifically and separately assessed using their preferred substrates and 2) histological changes in the gastric mucosa were systematically assessed by the Sydney systems (25). Seitz et al. (27) reported an inverse association between the degree of inflammation and the ADH activity in the gastric mucosa. Consistently, the present multiple regression analysis showed an inverse association between the class IV ADH activity and the development of inflammation in the human gastric mucosa. Simanowski et al. (28) suggested that development of inflammation causes a loss of normal cells expressing ADH and that this can explain why the ADH activities are reduced in the gastric mucosa with inflammation.

In the present study, we further demonstrated that progression of atrophy and intestinal metaplasia were also associated with decreasing class IV ADH activity in the human gastric mucosa even after adjusting subject age and $H. pylori$ infection status. Because loss of normal cells should occur also in gastric mucosa with atrophy or intestinal metaplasia, the reduction of class IV ADH activity in these specimens may be also just secondary to pathologic changes as mentioned by Simanowski et al. (28).

It was interesting to observe in the present study that the progressions of these morphological changes were inversely associated with the ATRA formation level in the human gastric mucosa. In that the class IV ADH is a key enzyme for the retinoic acid formation from retinol and its activity was inversely associated with the progression of inflammation, atrophy, or intestinal metaplasia, the findings per se were fully expected. However, it is notable that retinoic acid is an essential molecule for various cells to maintain their normal proliferation and differentiation (9). Moreover, the reduction of retinoic acid signal has been implicated in the development of premalignant lesions in the human gastric mucosa such as intestinal metaplasia and atrophy (12). Although retinoic acid should be systemically supplied to each cell, the significance of the regional retinoic acid supply system has recently been proposed (10, 30, 34). Taken together, contrary to the view that the pathologic changes result in the reduction of ADH activity, there is a possibility that the reduction of class IV ADH activity may cause pathologic changes in the gastric mucosa.

The current consensus is that $H. pylori$ infection plays a significant role in the pathogenesis of the human gastric mucosa.

closa (21). Interestingly, *H. pylori* infection has been reported to be associated with decreased ADH activity in the human gastric mucosa (4, 13, 17, 29). In view of our present findings, decrease of class IV ADH and the subsequent disturbance of retinoic acid supply may, at least in part, be involved in the mechanism by which *H. pylori* infection causes pathologic changes in the human gastric mucosa. The recently prevailing view is that *H. pylori* carries ADH and it may have various pathogenic roles (26). It is, therefore, postulated that exogenous *H. pylori* ADH may affect retinol metabolism in human gastric mucosa. However, it is most likely that the role of the *H. pylori* ADH on retinol oxidation is negligible in the human gastric mucosa because gastric mucosa with *H. pylori* infection have lower ADH activities as well as lower potential of retinol oxidation than that without it.

From the present findings, a scenario in which the sequence of the cell loss due to inflammation, the reduction of class IV ADH, and the disturbance of retinoic acid supply results in the development of various morphological changes in the gastric mucosa could be drawn. This is consistent with Correa cascade theory referring to the sequential development of various lesions in the gastric mucosa (5). The endpoint of the Correa cascade is the development of malignancy (5). Coincidently, insufficiency of retinoic acid supply also causes malignancies ultimately in various organs (31, 32), although it is still unclear that it causes gastric cancer.

The activity of class IV ADH was solely associated with the morphological changes in the human gastric mucosa among three gastric ADH isoforms. Similarly, Chrostek et al. (4) reported that *H. pylori* infection causes the exclusive reduction of class IV ADH activity in the human gastric mucosa. Differences in the localization of three ADH isoforms in the gastric mucosa (10) may, at least in part, account for the dissociation of effects of morphological changes on class IV ADH and those on the other ADHs. It is conceivable that the impact of cell loss is expected to be, at least, smaller on class III ADH compared with the other ADHs because class III ADH is broadly expressed in the gastric mucosa (10), whereas the other ADHs are localized in limited loci (10, 24). In addition, if the reduction of class IV ADH activity causes the morphological changes in the human gastric mucosa, this also could account for the exclusive association between the class IV ADH and the morphological changes in the human gastric mucosa.

Amounts of retinol, retinal, and retinoic acid in situ in the human gastric mucosa. A: subjects were divided into 3 groups according to degree of inflammation in the human gastric mucosa, and the level of the ATRA formation was determined in each group. As the degree of inflammation increased, the ATRA formation level decreased ($\lambda = 22.72, P = 0.0003$). *P* < 0.01 compared with group I. B: subjects were divided into 4 groups according to degree of intestinal metaplasia in the human gastric mucosa and the level of the ATRA formation was determined in each group. As the degree of intestinal metaplasia increased, the ATRA formation level had a tendency to decrease ($\lambda = 8.12, P = 0.0687$). *P* < 0.05 compared with group 0; *P* < 0.05 compared with group I. C: subjects were divided into 3 groups according to degree of atrophy in the gastric mucosa and the level of the ATRA formation was determined in each group. As the degree of atrophy increased, the ATRA formation level decreased ($\lambda = 10.80, P = 0.0116$); *P* < 0.05 compared with group I; *P* < 0.01 compared with group 2. Differences between groups were analyzed by one-way ANOVA. Each box indicates the range of 25–75% of each distribution, and the bar inside each box indicates the median of the distribution. Bars outside each box indicate the range of 10–90% of each distribution. Circles indicate the subject is out of the range of 10–90% of each distribution. Numbers in parentheses are numbers of subjects.
establishment of HPLC-MS (2, 18) may be applicable to detect these retinoids in situ.

In conclusion, among three gastric ADHs, class IV ADH is prominent in the production of retinoic acid from retinol. The progression of morphological changes such as inflammation, atrophy, and intestinal metaplasia in the gastric mucosa were associated with the reduction of class IV ADH activity as well as the decrease in retinoic acid supply. In that retinoic acid is a significant substance for maintaining normal morphology in various organs and the reduction of retinoic acid is implicated in the pathogenesis of premalignant lesions in the gastric mucosa, the reduction of class IV ADH activity may be a significant event leading to the development of morphological changes in the human gastric mucosa.
