Submitted 15 July 2010; accepted in final form 20 January 2011

Liou AP, Sei Y, Zhao X, Feng J, Lu X, Thomas C, Pechhold S, Raybould HE, Wank SA. The extracellular calcium-sensing receptor is required for cholecystokinin secretion in response to L-phenylalanine in acutely isolated intestinal I cells. Am J Physiol Gastrointest Liver Physiol 300: G538–G546, 2011. First published January 20, 2011; doi:10.1152/ajpgi.00342.2010.—The extracellular calcium-sensing receptor (CaSR) has recently been recognized as an L-amino acid sensor and has been implicated in mediating cholecystokinin (CCK) secretion in response to aromatic amino acids. We investigated whether direct detection of L-phenylalanine (L-Phe) by CaSR results in CCK secretion in the native I cell. Fluorescence-activated cell sorting of duodenal I cells from CCK-enhanced green fluorescent protein (eGFP) transgenic mice demonstrated CaSR gene expression. Immunostaining of fixed and fresh duodenal tissue sections confirmed CaSR protein expression. Intracellular calcium fluxes were CaSR dependent, stereoselective for L-Phe over D-Phe, and responsive to L-Phe in the presence of physiological (1.26 mM) and superphysiological (2.5 mM) extracellular calcium concentrations, respectively. While the deletion of CaSR from CCK-eGFP cells did not affect basal CCK secretion, the effect of L-Phe or cinacalcet on intracellular calcium flux was lost. In fact, both secretagogues, as well as superphysiological Ca2+ elevated an unexpected 20–30% decrease in CCK secretion compared with basal secretion in CaSR KO CCK-eGFP cells. CCK secretion in response to KCl or tryptophan was unaffected by the absence of CaSR. The present data suggest that CaSR is required for hormone secretion in the specific response to L-Phe by the native I cell, and that a receptor-mediated mechanism may inhibit hormone secretion in the absence of a fully functional CaSR.

amino acid sensing; protein sensing; enteroendocrine

Dietary protein is satiating, in part, due to the release of cholecystokinin (CCK) from duodenal enteroendocrine “I” cells. Aromatic amino acids, particularly L-phenylalanine (L-Phe), are known to elevate plasma CCK levels and reduce food intake in humans (2), rhesus macaques (14), and rats (1). Additionally, in the murine enteroendocrine cell line STC-1, L-Phe activates calcium channels and intracellular signaling pathways, resulting in CCK secretion (21).

The extracellular calcium-sensing receptor (CaSR) was originally cloned from the bovine parathyroid gland (5) and is well established for its role in serum calcium homeostasis (17, 19). This G protein-coupled receptor is directly activated in response to inorganic and organic polycations and is also allosterically activated by phenylalkylamine type II calcimimetics and aromatic L-amino acids, such as L-Phe, in the presence of physiological calcium concentrations (12). The CaSR has been proposed to function as an L-amino acid sensor and as a mediator of hormone secretion in the gastrointestinal tract. Indeed, among other tissue types, the CaSR has also been localized on the pancreatic β-cell (33, 39), enteric endocrine cells of the colonic mucosa (39), and gastric-secreting G cells of the stomach (34).

Given that L-Phe is a known CCK secretagogue, the possibility remains that the CaSR mediates amino acid-induced CCK secretion by the I cell (11). In a recent STC-1 cell study, phenylalanine-induced mobilization of intracellular calcium and CCK secretion was inhibited with the allosteric CaSR inhibitor NPS2143 (16), further supporting a putative role for the CaSR in CCK secretion. However, it is unknown whether this receptor is functionally expressed by the native intestinal I cell, and whether it functions to regulate L-amino acid-induced CCK secretion as a nutrient sensor.

In this study, we tested the hypothesis that the CaSR serves as an amino acid sensor, modulating L-Phe-induced CCK secretion from native intestinal I cells isolated from CCK-enhanced green fluorescent protein (eGFP) mice. We demonstrate that CaSR is expressed on these cells and is required for hormone secretion in response to direct stimulation with L-Phe, and that this response is enhanced in the presence of additional extracellular calcium.

MATERIALS AND METHODS

Materials. L-Phe, D-Phe, and CaCl2 (cell culture grade) were purchased from Sigma (St. Louis, MO). Tryptophan, a pancreatic digest of casein, was obtained from BD Biosciences (San Jose, CA). Cinacalcet was purified from Sensipar (Amgen, Thousand Oaks, CA).

Experimental animals. Transgenic mice with CCK promoter-driven eGFP were obtained from the Mutant Mouse Regional Resource Center (Davis, CA) and were used as the wild-type (WT) control (CaSR+/+ PTH+/+ CCK-eGFP) for acutely isolated cell studies. CaSR and parathyroid hormone (PTH) double homozygous knockout (KO) mice (a generous gift of Drs. Claudine Kos and Martin Pollack, Brigham and Women’s Hospital) were previously derived and characterized (19). Knocking out the PTH was required to rescue the CaSR−/− phenotype from bone abnormalities and premature death and was assumed to not affect gastrointestinal hormone secretion (17). The CaSR and PTH double homozygous KO mice (CaSR−/−/PTH−/−) were previously derived (KO) mice (a generous gift of Drs. Claudine Kos and Martin Pollack, Brigham and Women’s Hospital) were previously derived.
PTH$^{-/-}$ were crossed with the CCK-eGFP transgenic mice to evaluate the functional role of CaSR in isolated CCK-eGFP cells. Animals were bred and maintained according to the National Institutes of Health Institutional Animal Care and Use Committee (ACUC) guidelines, following independent protocol review and approval by the National Institute of Diabetes and Digestive and Kidney Diseases ACUC.

**Mouse genotyping.** Tail DNA was extracted using hot 50 mM NaOH and 1 M Tris-HCl, pH 8.0. Genomic DNA samples were amplified for CaSR and PTH using primers described previously (19). Presence of the eGFP transgene was determined using the following primers: EGFP-F1, 5′CCA CCA GTG CAG CTT GTC C 3′; and EGFP-R1, 5′GTA CTC CAG CTT GTG C 3′. All PCR reactions were performed using the Invitrogen Platinum Taq DNA Polymerase High Fidelity system (Invitrogen, Carlsbad, CA) with 35 cycles of 94°C for 2 min, 94°C for 30 s, 55°C for 30 s, and 68°C for 45 s to 1 min, with a final 7-min extension at 68°C. Amplified samples were resolved on a 1.5% ethidium-bromide-stained agarose gel and examined for positive band products of the appropriate sizes.

**Isolation of intestinal endocrine cells.** Adult mice were euthanized, and a 5- to 6-cm proximal segment of duodenum was collected, washed, and incubated in 1 mM EDTA-Dulbecco’s phosphate-buffered saline (DPBS) solution for 20 min in a 37°C shaking water bath. After washing, tissue was incubated for another 20 min in 50–75 U/ml collagenase (Worthington Chemical, CLPSA grade) in cell culture media. Cells were resuspended and filtered through 30-μm and 20-μm nylon filters (Spectrum Laboratories, Laguna Hills, CA) to obtain a dispersed single-cell population. Cells were washed, resuspended in fluorescent-activated cell sorting (FACS) sorting buffer (5% PBS, 50 μg/ml DNase I in phenol-free DMEM), and underwent FACS (BD FAC S ARIA machine, BD Biosciences, San Jose, CA).

Approximately 30,000 eGFP cells were sorted based on GFP fluorescence (Fig. 1, A and B) and collected into a tube with 10% FBS-phenol-free DMEM. For RT-PCR studies, a non-eGFP cell population (FITC < 10$^3$), comprising primarily of enterocytes, but may also include goblet cells, lymphocytes, and non-eGFP endocrine cells, was simultaneously sorted into a separate collection tube. Examination of isolated eGFP cells demonstrated minimal to no mRNA contamination from enterocytes or goblet cells (data not shown), and were confirmed to be both GFP and CCK immunopositive (Fig. 1,C).

**Immunofluorescent staining.** For confirmatory studies, FAC-sorted eGFP cells were dried on positively charged slides, washed in PBS, and stained with a 1:2,000 dilution of rabbit anti-CCK antibody (Peninsula Laboratories, Torrance, CA) and a 1:1,000 dilution of mouse anti-GFP in 1% bovine serum albumin (BSA)-PBS overnight at 4°C. After washing, slides were incubated for 1 h with Alexafluor 594 goat anti-rabbit IgG secondary antibody and Pacific Blue conjugated goat anti-mouse IgG secondary antibody (Invitrogen).

For CaSR immunostaining of whole tissue sections, previously genotyped mice were euthanized and intracardially perfused with cold 0.9% NaCl, followed by fixation with fresh cold 4% paraformaldehyde (PFA) in PBS. Stomach antrum and ~2–3 cm of proximal duodenum were collected, trimmed of pancreatic tissue, and submerged in 4% PFA-PBS for 2–3 h at room temperature before final rinse with PBS and transfer into 70% ethanol. Tissue was submitted to Histoserv (Germantown, MD) for paraffin embedding and sectioning (5-μm slices). Sections were deparaffinized, rehydrated, and underwent antigen retrieval, as previously described (15). Briefly, slides were placed in a beaker containing citrate buffer solution (pH 6.0) with 0.1% Tween and boiled over a hotplate for 40 min. The sections were immediately cooled in Tris-buffered saline (0.05 mol/l; pH 7.6) containing 5% goat serum for 30 min, followed by incubation with PBS blocking buffer containing 3% BSA for 30 min. Sections were incubated with either 1:200, 1:500, or 1:1,000 dilutions of mouse monoclonal anti-human CaSR antibody (ADD: Affinity Bioreagents, Rockford, IL) in blocking buffer for 1 h at room temperature. Fresh coverslips were remounted, and slides were viewed under confocal microscopy with LP560 and BP 505–530 emission filters to ensure no bleed-through of green fluorescence into the red spectrum. Slides with a CaSR dilution of 1:500 and 1:1,000 were most optimal. A similar procedure was followed, with the fluorescent spectra of the secondary antibodies reversed. For immu-
nostaining of fresh tissue, duodenal villus samples were isolated by incubation in 2 mM EDTA-DPBS (30 min, 4°C), followed by gentle pipetting and centrifugation (250 g, 2 min). The villus samples were immediately incubated with mouse anti-CaSR monoclonal antibody (1:50; MA1–934, Thermo Scientific, Fremont, CA) for 30 min at 4°C, centrifuge washed, and incubated with the appropriate Alexa Fluor 633 anti-mouse IgG secondary antibody (Invitrogen) for 30 min at 4°C in 1% BSA-DPBS. After being washed twice with cold DPBS, immunostained villi were fixed with 4% PFA and analyzed by confocal microscopy.

**RNA extraction and RT-PCR.** RNA was extracted from FAC-sorted CCK-eGFP-positive cells and non-eGFP cells with Trizol Reagent (Invitrogen) and 20% phenol-chloroform isomyl-alcohol (Invitrogen). The aqueous phase was ethanol precipitated and resuspended in 11.5 μl of DPEC water. Reverse transcription of total RNA was performed using the High-Capacity cDNA Reverse Transcription Kit (Applied Biosystems, San Jose, CA) and run under the following thermocycler conditions: 10 min at 25°C, 60 min at 50°C, and 5 min at 94°C. The qPCR reaction was performed using an Applied Biosystems Step One System with a 20-μl reaction volume made of 2× master mix (with 1 μl target probe), 2× assay mix, 10× amplified cDNA sample, and water using optimized target probes (Applied Biosystems) for CaSR (Mm00443375_m1), Tas1R3 (Mm00473459_g1), slc15a1; Mm00453524_m1). The ABI preset cycling conditions were calculated as 2^(-ΔΔCt) using the CCK-eGFP cell population relative to the non-eGFP cell populations as the calibrator. Statistical significance was determined using a paired t-test between the eGFP and non-eGFP cell populations. T1R1 transcript was undetectable in both populations. Gene fold expression of 1 is regarded as equivalent to the expression in the non-eGFP cell population. T1R1 transcript was undetectable in both populations. Gene fold expression of 1 is regarded as equivalent to the expression in the non-eGFP cell population.

**RESULTS**

**CCK-eGFP cells express CaSR.** Using quantitative RT-PCR, a pure population of acutely isolated CCK-eGFP cells (Fig. 1) was compared with a non-eGFP cell population for the presence of CaSR mRNA transcripts (Fig. 2). Out of five separate non-eGFP cell populations, only two populations yielded detectable CaSR gene expression with a Ct value < 40. To calculate relative gene expression with a ΔCt value, the Ct values of the other three populations were set to 40. Using this overestimated ΔCt value for non-eGFP cells, we calculated that CCK-eGFP cells expressed at least 900-fold greater CaSR transcript than non-eGFP cells (Fig. 2; P < 0.0001). The expression for T1R3 was equivalent between CCK-eGFP and non-eGFP cells, but T1R1 expression was not detectable in either population. In addition, mRNA expression for putative peptone receptor GPR92 and the oligopeptide transporter.
PepT1 was equivalent between CCK-eGFP and non-eGFP cells.

Given the differential gene expression for CaSR in CCK-eGFP cells compared with non-eGFP cells, the presence of CaSR protein was confirmed with immunofluorescent staining in antigen-retrieved, paraffin-embedded duodenal tissue (Fig. 3A) and on the cell surface of eGFP-positive cells from nonfixed and nonpermeabilized fresh duodenal vili (Fig. 3B) of CaSR+/+ PTH+/+ CCK-eGFP transgenic mice. For fixed tissue sections, all CCK immunoreactive cells were CaSR positive, with true CaSR immunoreactivity accepted as whole cell staining at all optical planes (Fig. 3, A1–A3). The same staining pattern was evident when the secondary antibody of the opposite emission spectra was reversed (Fig. 3, A7–A9). No secondary nonspecific staining was evident with exclusion of the primary antibody in both tissue sections (Fig. 3, A4–A6) and in fresh duodenal vili (data not shown).

Intracellular Ca2+ flux in response to Phe is stereo selective and CaSR dependent in CCK-eGFP cells. To examine whether CCK-eGFP cells express functional CaSR that can respond to amino acids in a stereoisomer-selective fashion, CCK-eGFP cells were tested for an intracellular Ca2+ response to L-Phe and D-Phe by confocal Ca2+ imaging (Fig. 4). In CaSR+/+ CCK-eGFP cells, L-Phe (20 mM, n = 11) significantly induced a time-dependent increase in relative FI of Quast Rhod4 (i.e., [Ca2+]i; P < 0.0001), which was significantly greater than the lower [Ca2+]i flux observed in response to D-Phe (20 mM; n = 9; P < 0.001; Fig. 4A, top graph). This differential response between L-Phe and D-Phe was eliminated in the absence of CaSR (n = 6 and n = 4, respectively; Fig. 4A, bottom graph).

Targeted deletion of CaSR inhibits CCK secretion in acutely isolated CCK-eGFP cells. To evaluate the functional role of CaSR on CCK secretion, separately isolated CaSR+/+ PTH+/+ (CaSR+/+) and CaSR−/− PTH−/− (CaSR−/−) CCK-eGFP cells were subjected to various ligands, and CCK released in the supernatant was measured by radioimmunoassay. Baseline secretion at normal physiological calcium (1.26 mM) concentrations was not significantly different between CaSR+/+ and CaSR−/− CCK-eGFP cells, measured as 5.8 ± 0.9 and 6.0 ± 0.9% of total CCK content, respectively. In CaSR+/+ CCK-eGFP cells, L-Phe (30 mM) significantly increased CCK secretion (P < 0.05; Fig. 5A). Moreover, additional extracellular calcium (superphysiological at 2.5 mM) enhanced this response by approximately twofold. In contrast, L-Phe did not stimulate CCK secretion in CaSR−/− CCK-eGFP cells at both calcium concentrations (Fig. 5B); however, a trend toward a 20–30% decrease in CCK secretion, relative to basal, was evident. Superphysiological calcium alone caused a slight, but insignificant, increase in CCK secretion in CaSR+/+ CCK-eGFP cells. Similar to what was observed with L-Phe, a trend toward reduced secretion was also observed in CaSR−/− CCK-eGFP cells in response to superphysiological calcium. Tryptophan (1%) elicited a significant increase in CCK secretion in CaSR+/+ CCK-eGFP cells (P < 0.05), but not in the CaSR−/− CCK-eGFP cells. Although not significantly different from baseline, D-Phe caused a trend toward an increase in CCK secretion in both CaSR+/+ and CaSR−/− CCK-eGFP cells. Both cell populations were equally and significantly responsive to KCl (P < 0.01), which was used to assess intra-assay cell viability and secretory potential.

Targeted deletion of CaSR abolishes intracellular Ca2+ flux and negatively inhibits CCK secretion in response to cinacalcet in CCK-eGFP cells. Type II calcimimetic, cinacalcet, was used to further assess whether the intracellular calcium response and CCK secretion in CCK-eGFP cells was CaSR specific. A 1,000 nM dose has been shown previously to allosterically activate the CaSR (29). The same dose induced an intracellular Ca2+ response in CasR+/+ CCK-eGFP cells (n = 16) that was significantly greater than the response

Fig. 3. Immunohistochemical colocalization of CaSR on CCK-expressing enteroendocrine cells. A: CCK-immunoreactive enteroendocrine cells express CaSR (arrows, asterisks) in paraffin-embedded duodenal tissue sections of CaSR+/+ PTH+/+ CCK-eGFP transgenic mice. CCK immunolabeling was concentrated on the basilar aspect of isolated cells. CaSR-specific immunostaining was distinguished from the high background nonspecific staining of nuclei within these sections by visualizing whole cell CaSR immunostaining throughout all microscopic focal planes within CCK-immunopositive cells. Primary antibody (Ab) was excluded in tissue sections represented in A4–A6, A1–A3, with primary Ab; A7–A9, primary Ab reversed. B: expression of CaSR in CCK-eGFP+ cells in fresh primary duodenal vili from CaSR+/+ CCK-eGFP transgenic mice. Inset: an enlarged CaSR-positive CCK-eGFP cell outlined in the villus demonstrating CaSR expression localized to the cell surface.
observed in CaR<sup>−/−</sup> CCK-eGFP cells (n = 10; P < 0.0001; Fig. 6, A and B). Baseline CCK secretion with a 0.05% DMSO-HHBSS vehicle, relative to total CCK content, was similar in both CaSR WT (6.4 ± 0.8%, n = 6) and KO (6.6 ± 0.7%, n = 5) CCK-eGFP cells. A modest trend toward increased CCK secretion was observed in CaSR<sup>−/−</sup> CCK-eGFP cells given 1,000 nM cinacalcet, while the same dose caused a significant decrease in CCK secretion (Fig. 6C; P < 0.05). Additionally, both cell types were equally responsive to 50 mM KCl (data not shown).

**DISCUSSION**

In this study, we provide evidence that the extracellular CaSR is expressed on native intestinal I cells at a gene and protein level. Isolation of native I cells from CCK-eGFP mice or CCK-eGFP mice bred to CaSR PTH double homozygous KO mice enabled evaluation of the CaSR for its putative role in directly mediating CCK secretion in response to L-Phe. Our studies revealed that CCK-eGFP cell activation is CaSR dependent and that CCK secretion in response to direct stimulation with L-Phe is enhanced in the presence of superphysiolog-
Fig. 6. Effect of cinacalcet on intracellular Ca\(^{2+}\) flux and CCK secretion from I cells in the presence or absence of CaSR. A: representative time courses of changes in [Ca\(^{2+}\)]\(_i\), in Quest Rhod4-loaded CCK-eGFP cells stimulated with cinacalcet (1 μM). ▲, CaSR\(^{+/+}\); ◊, CaSR\(^{-/-}\); arrow, time of stimulation. B: mean maximum %increase (± SE) in the FI of Quest Rhod4 relative to the baseline ([peak FI - basal FI]/basal FI × 100) in CaSR\(^{+/+}\) (n = 16) vs. CaSR\(^{-/-}\) (n = 10) CCK-eGFP cells after stimulation with cinacalcet, 1 μM. ****P < 0.0001 with unpaired t-test. C: CCK released in the supernatant of sorted CaSR\(^{+/+}\) (solid bar) and CaSR\(^{-/-}\) (open bar) CCK-eGFP cells incubated with cinacalcet (1 μM). Results are presented as %change (means ± SE) from baseline secretion in 0.05% DMSO-HHBSS vehicle alone. N = 5–7 separate cell populations with each condition performed and sampled in triplicate. *P < 0.05.

Aside from calcium-regulating tissue types, the CaSR is also found in pancreatic β-cells (41) and gastrointestinal endocrine cells, including gastrin secreting G cells in the stomach (34) and chromogranin A-staining cells throughout the intestine (39). CaSR transcript is also evident in the STC-1 cell line (16), suggesting that CaSR expression is specific to neuroendocrine cells. Conflicting evidence localizing CaSR protein throughout the basilar aspect of absorptive duodenal epithelial cells exists (7). However, our qPCR findings in isolated CCK-eGFP cells and immunochemical staining confirm that CaSR is expressed in duodenal CCK-secreting enteroendocrine cells and not absorptive epithelial cells. We cannot rule out, however, the possibility that other enteroendocrine cell types express the CaSR.

We also evaluated isolated CCK-eGFP cells for transcripts of the umami taste receptor, since taste receptor signaling components have been found within isolated cells of the intestinal epithelium (3) and in the STC-1 cell line (13). This heterodimeric complex of G protein-coupled receptors T1R1 and T1R3, originally described in taste buds of the tongue (28), presented as a potential alternative amino acid receptor to the CaSR in the enterodendocrine cell. However, since T1R1 subunit transcripts were undetectable in our samples, we considered it unlikely that this taste receptor is involved in amino acid detection by the native I cell.

Given that aromatic amino acids allosterically activate the CaSR and that [Ca\(^{2+}\)]\(_o\) is essential for hormone secretion, the CaSR is a reasonable candidate for mediating L-Phe-induced CCK secretion in the native I cell. Indeed, [Ca\(^{2+}\)]\(_o\) and L-Phe synergistically increase intracellular calcium flux and CCK secretion in the STC-1 cell (16), mirroring the pharmacological profile of the CaSR (12). And, in our isolated CCK-eGFP cells, L-Phe directly caused a significant increase in intracellular calcium and CCK secretion, the secretion of which was enhanced in the presence of superphysiological [Ca\(^{2+}\)]\(_o\) levels. Calcium is a primary agonist for the CaSR, whereas L-Phe requires the presence of calcium to allosterically increase CaSR sensitivity to [Ca\(^{2+}\)]\(_o\) (12). Interestingly, superphysiological [Ca\(^{2+}\)]\(_o\) levels alone failed to significantly increase CCK secretion in isolated CCK-eGFP cells. It is well established that extracellular calcium influx by way of L-type calcium channels is required for secretion in response to various nutrients, including L-Phe, in both the STC-1 cell line and in intestinal mucosal cells (21, 25, 30, 38). Removal of [Ca\(^{2+}\)]\(_o\) with EGTA reduces CCK secretion in response to bombesin (40), pepotone, and peptidomimetic antibiotics (30) in STC-1 cells, as well as in perfused rat intestinal mucosal cells in response to monopeptide (4), bombesin (38), and the calcium ionophore A23187 (4). However, unlike the parathyroid cell (5) or even the G cell (6), luminal calcium is not a recognized secretagogue for the I cell. Therefore, although [Ca\(^{2+}\)]\(_o\) is a requirement for secretory responses to various secretagogues, it alone is not sufficient enough to evoke hormone secretion from the native I cell.

Through interactions with different G proteins, other membrane proteins, and cytoskeletal elements, the CaSR can transduce various signals to regulate specific cellular functions,
ranging from cell division and differentiation to hormone secretion (18). [Ca\(^{2+}\)]\(_i\), aromatic amino acids, and calcimimetics bind different sites of the CaSR (26, 27, 46, 47), which may influence which signaling pathway is activated. Indeed, [Ca\(^{2+}\)]\(_i\) and L-Phe activation of the CaSR results in transduction of different signaling pathways and intracellular Ca\(^{2+}\) oscillation patterns (35, 36). [Ca\(^{2+}\)]\(_i\) activation increases inositol trisphosphate production and intracellular Ca\(^{2+}\) flux through a G\(_q\) signaling pathway, while L-Phe targets a G\(_{12/13}\) and the Rho ATPase pathway to allow [Ca\(^{2+}\)]\(_i\) entry via the cation channel canonical transient receptor potential 1 (35, 36). The observation that L-Phe, and not [Ca\(^{2+}\)]\(_i\), increased hormone secretion, and that the type II allosteric activator calcimimetic cinacalcet trends but does not significantly increase CCK secretion, despite an increase in [Ca\(^{2+}\)]\(_i\) in isolated CCK-eGFP cells, suggests that L-Phe specifically directs a dominant signaling pathway potentiating hormone secretion. Allosteric activation of the CaSR by L-Phe would also activate [Ca\(^{2+}\)]\(_i\)-mediated signaling, and the interaction of both pathways may explain the secretary response to L-Phe in the presence of [Ca\(^{2+}\)]\(_i\) and the enhancement of hormone secretion with additional [Ca\(^{2+}\)]\(_i\).

Therefore, the CaSR may specifically function in the I cell as a predominately aromatic amino acid sensor, mediating hormone secretion in response to L-Phe.

To ensure that the enhanced secretory response to L-Phe in the presence of additional [Ca\(^{2+}\)]\(_i\) was specific to the CaSR rather than through an alternative nutrient sensor, we measured CCK secretion in CCK-eGFP cells isolated from CaSR null animals, expecting that targeted deletion of the CaSR would render the native I cell unresponsive to L-Phe. Absence of the CaSR not only prevented CCK secretion in response to [Ca\(^{2+}\)]\(_i\) and L-Phe, but a trend toward a reduction in secretion, below that of baseline, was observed. This response was specific to allosteric activators or agonists of CaSR and not to a more heterogeneous protein hydrolysate mixture or to the weaker N-Phe isomer (12), whose modest effect is likely nonspecific to CaSR activation. Hormone secretion in response to CaSR-independent secretagogue KCl was also unaffected in the absence of the CaSR. Moreover, a significant reduction in secretion relative to baseline was observed in CaSR KO CCK-eGFP cells given type II calcimimetic cinacalcet. The specificity of this change in secretory behavior in response to CaSR ligands in the absence of CaSR further supports a role for CaSR in CCK secretion. In addition, a receptor-mediated inhibitory pathway appears to have been unmasked in the absence of CaSR expression that clearly reduces secretory function to CaSR-specific ligands.

The mechanism by which CaSR agonists and allosteric activators cause this reduction in secretion in CaSR KO CCK-eGFP cells is unclear, but it is unlikely that the effect is due to decreased cellular excitability. ATP-sensitive K\(^+\) channels regulating basal membrane potential (20, 23) can be affected by CaSR. However, there was no difference in basal secretion between CaSR WT and KO CCK-eGFP cells. Rather, another mechanism that binds similar ligands may be involved. A CaSR splice variant that lacks exon 5, which is believed to encode the [Ca\(^{2+}\)]\(_i\) binding region of the NH\(_2\)-terminus, has previously been shown to be expressed within epidermal cells of the CaSR\(^{+/−}\) mice used in our laboratory’s studies (31). The CaSR\(^{+/−}\) mice contain a neomycin cassette within exon 5, preventing functional expression of full-length CaSR (17), but the splice variant appears to remain intact in various tissues (31). Coexpression of the CaSR splice variant reduces downstream intracellular calcium flux and inositol trisphosphate production in response to [Ca\(^{2+}\)]\(_i\), in human keratinocytes (32). Further studies would be important and necessary to evaluate the expression of the CaSR splice variant in the intestinal I cell, and whether this splice variant is driving an inhibitory signaling pathway, reducing hormone secretion in response to CaSR-mediated secretagogues.

It is also possible that the CaSR is coupled to other ion channels regulating intracellular Ca\(^{2+}\) entry. Besides the cation channel canonical transient receptor potential 1 (35, 36), thapsigargin sensitive nonselective cation channels have also been linked to CaSR activation and membrane depolarization in several neuronal cell types, such as murine hippocampal pyramidal cells, rat hippocampal cells, CaSR transfect human embryonic kidney-293 cells, and presynaptic neurons (44–45), as well as in insulin secreting β-cells and gastrin secreting G cells (42). Studies in murine neocortical neurons and human astrocytoma cell lines suggest a regulatory role of CaSR on calcium-dependent K\(^+\) channels influencing membrane excitability (8, 43). Whether coupling of either of these channels to CaSR, or perhaps L-type calcium channels that drive [Ca\(^{2+}\)]\(_i\) entry into the cell (22), has an effect on CCK secretion remains to be elucidated.

Tryptone significantly increased CCK secretion in CaSR WT CCK-eGFP cells, but, in the absence of CaSR, tryptone’s stimulatory effect is no longer significant from baseline. Being an enzymatic digest of casein, tryptone contains a heterogeneous mixture of single amino acids and peptides. By genetically deleting the CaSR, any stimulatory effect from the amino acid component of tryptone would be lost. However, unlike what was observed in response to L-Phe, [Ca\(^{2+}\)]\(_i\), and cinacalcet, tryptone continues to display an upward trend in CCK secretion. This may be due to the presence of other membrane protein receptors that sense peptides. Such candidates include the peptone receptor GPR92/93 (10) and the proton-coupled oligopeptide transporter PepT1 (24), whose gene expression was demonstrated in the initial qPCR screening of CCK-eGFP cells. However, given that neighboring enterocytes also possess GPR92 (9) and PepT1 (37), further studies are required to determine whether these candidates have a direct, rather than an indirect, effect on hormone secretion in the native cell.

Given the present findings, we suggest that the CaSR offers a functional role for cellular activity in response to L-Phe. The mechanism requires further study, but we hypothesize that the CaSR modulates signaling pathways that open calcium channels, allowing [Ca\(^{2+}\)]\(_i\) entry and intracellular Ca\(^{2+}\) influx leading to CCK secretion. In the absence or antagonism of CaSR, a receptor-mediated inhibitory pathway (perhaps mediated by the CaSR splice variant) is activated to prevent secretory vesicle release, resulting in the inhibition of hormone secretion. This inhibitory pathway may also explain the negative trend that is seen in response to CaSR-specific ligands in the CaSR\(^{+/−}\) CCK-eGFP cells. It is becoming increasingly apparent that multiple modalities for the detection of dietary protein digestive products exist, illustrating the complexity of nutrient sensing in enteroendocrine cells.
