Heredia DJ, Grainger N, McCann CJ, Smith TK. Insights from a novel model of slow-transit constipation generated by partial outlet obstruction in the murine large intestine. Am J Physiol Gastrointest Liver Physiol 303: G1004–G1016, 2012. First published September 6, 2012; doi:10.1152/ajpgi.00238.2012.—The mechanisms underlying slow-transit constipation (STC) are unclear. In 50% of patients with STC, some form of outlet obstruction has been reported; also an elongated colon has been linked to patients with STC. Our aims were 1) to develop a murine model of STC induced by partial outlet obstruction and 2) to determine whether this leads to colonic elongation and, consequently, activation of the inhibitory “occult reflex,” which may contribute to STC in humans. Using a purse-string suture, we physically reduced the maximal anal sphincter opening in C57BL/6 mice. After 4 days, the mice were euthanized (acutely obstructed), the suture was removed (relieved), or the suture was removed and replaced repeatedly (chronically obstructed, over 24–31 days). In partially obstructed mice, we observed increased cyclooxygenase (COX)-2 levels in muscularis and mucosa, an elongated impacted large bowel, slowed transit, nonpropagating colonic migrating motor complexes (CMMCs), a lack of mucosal reflexes, a depolarized circular muscle with slow-wave activity due to a lack of spontaneous inhibitory junction potentials, muscle hypertrophy, and CMMCs in mucosa-free preparations. Elongation of the empty obstructed colon produced a pronounced occult reflex. Removal of the obstruction or addition of a COX-2 antagonist (in vitro and in vivo) restored membrane potential, spontaneous inhibitory junction potentials, CMMC propagation, and mucosal reflexes. We conclude that partial outlet obstruction increases COX-2 leading to a hyperexcitable colon. This hyperexcitability is largely due to suppression of only descending inhibitory neural pathways by prostaglandins. The upregulation of motility is suppressed by the occult reflex activated by colonic elongation.

CHRONIC SLOW-TRANSIT CONSTIPATION (STC) remains a challenge for today’s gastroenterologists. Traditional treatments include increased fiber intake, osmotic laxatives, stimulant laxatives, prokinetic agents, biofeedback training, and surgery. These often are tried sequentially and episodically, with little evidence of long-term efficacy (29). Most commonly, the symptoms of STC are not alleviated; rather, STC is only managed throughout the patient’s life (17). The mechanisms underlying STC are unclear, since hypo- and hypercontractility have been observed (8). Constipation is a common and costly complaint, affecting ~15% of the US population. According to the Rome III criteria, patients are generally considered to have STC if they exhibit slow fecal transit and more than two of the following symptoms: straining during defecation, hard or proctubered stool, incomplete evacuation, sensation of blockage, manual mechanical evacuation, and less than three defecations per week (14, 15).

Chronic constipation is known to include outlet obstruction, colonic inertia, or both; in fact, most patients with colonic inertia have associated outlet obstruction (27, 39). It has been reported that >50% of all patients with STC have some form of outlet obstruction, which can be due to a variety of causes, including defective rectal filling sensation, idiopathic megacolon with or without megacolon, rectal hyposensitivity (blunted rectum), functional outlet obstruction, or inefficient inhibition of the internal anal sphincter (9, 28). Surgical intervention is considered a therapeutic option for patients with STC who do not respond to aggressive medical therapy (38). “Failure to address the outlet obstruction might explain the high rate of re-operation reported in most series of patients undergoing colectomy for colonic inertia” (27).

Luminal distension or mucosal stimulation of the colon evokes the peristaltic reflex, which consists of a contraction and relaxation above and below the stimulated region, respectively, due to activation of intrinsic ascending excitatory and descending inhibitory neural reflex pathways, respectively (4, 5, 11, 30, 36). Recent studies have characterized a conserved inhibitory reflex in guinea pig (10, 11, 36), mouse (19), and monkey (Dickson and Smith, unpublished observations) large intestine that is triggered by colonic elongation, rather than distension. Referred to as the “occult” (i.e., hidden from view) reflex, this phenomenon is responsible for depressing intrinsic nerve pathways underlying the peristaltic reflex and colonic migrating motor complexes (CMMCs), rather than a direct muscle response. When stretched longitudinally, mechanosensitive descending neuronal nitric oxide (NO) synthase (nNOS)-positive interneurons release NO to depress the intrinsic neural circuitry [interneurons and afterhyperpolarizing (AH) neurons] (10, 11, 19). Normally, the occult reflex allows the colon to accumulate and store fecal matter. Typically, the colon will elongate to accommodate contents, while only slight circumferential dilations occur (10, 11, 17).

Recently, the occult reflex was suggested to contribute to STC in humans, because “Interestingly we have observed that many patients with slow transit constipation have an elongated transverse colon” (32, 33). Historically, an elongated colon was believed to be associated with STC (reviewed in Refs. 14 and 19): “The most common related cause of constipation after ARM (anorectal myectomy) was a redundant colon” (39). Barium enema X-ray studies confirmed an elongated colon in patients with STC (26, 32, 33). Also called a redundant or dolichocolon (Dolichos, a Greek long-distance runner), elongated colons were at times surgically shortened; however, this method of treatment was not successful.

To further investigate the role of the occult reflex on slow-transit intestinal disorders, we have used partial outlet obstruction to develop a simple mouse model of STC that displays the phenotype of an elongated colon. Few animal models of constipation obstruction exist; most have problematic methods of implementation, since they require significant invasive surgical intervention or use opiate drugs or serotonin receptor (5-HT3) antagonists, which impede neurotransmission (14). A suitable animal model of STC is needed to begin to understand its mechanisms, so that new and more effective therapies can be developed for this chronic disorder. The aim of this study was to develop a drug-free, easily inducible murine model of STC that parallels some of the changes observed in the human condition.

METHODS

Male C57BL/6 mice (28–42 days old) were euthanized by inhalation of a 5% concentration of isoflurane, followed by cervical dislocation. These studies were performed in accordance with National Institutes of Health guidelines for the use and care of laboratory animals, and all procedures were approved by the Animal Ethics Committee and the Institutional Animal Care and Use Committee at the University of Nevada, Reno.

Partial Reduction of the External Anal Sphincter Opening

A simple local procedure that does not require a laparotomy was used to cause partial outlet obstruction in mice to reduce daily fecal output. Anesthesia was induced with 3–4% isoflurane and maintained at 1–3%. The perianal area of the animal was prepared with a Betadine scrub prior to lidocaine injection. Lidocaine (2%, up to 0.25 ml as needed) was injected into the skin surrounding the perianal area. A smooth 2.5-mm-diameter glass rod was inserted into the anus. A purse-string suture (size 6-0, Prolene, Ethicon, San Lorenzo, Puerto Rico) was placed in the external perianal region to close the lumen of the anus around the glass rod; then the rod was removed. The mouse was revivified and observed for 4 days until it was euthanized or until the suture was removed. In animals that required suture removal, anesthesia was induced as described above, the suture was removed, and the animal was revivified. In acute partially obstructed animals, the suture remained for 3–4 days and was removed for 4–5 days, and the process was repeated three additional times (over 24–31 days). In relieved animals, the suture was removed for 7 days following partial obstruction. During model development, animals obstructed for >5 days exhibited signs of stress (arched back and a lack of foraging) and occasionally a twisted necrotic small intestine (volvulus; 4 of 40 mice).

Preparations

A ventral midline incision was made in the animal, the gastrointestinal tract (stomach to external anal sphincter) was carefully excised, and several preparations were derived.

Artificial pellet propulsion. An isolated segment of colonic tissue was pinned taut in a Sylgard (WPI, Sarasota, FL)-lined organ bath continuously perfused with oxygenated Krebs-Ringer bicarbonate solution (see Drugs and Solutions) at 36.0 ± 0.5°C. An artificial pellet was inserted into the oral end, and the movement was recorded with a video camera (model WV-BP330, Panasonic CCTV) directly to a computer (iMac, Apple, Cupertino, CA) and analyzed using previously described methods (13, 19).

Tension recordings of CMMCs. Three isometric tension transducers (model TST125C, Biopac Systems, Santa Barbara, CA) were attached by suture silk at regular intervals [proximal colon (To), at the colonic flexure (Tm), and 10–15 mm from the anal end (Ta)]; the silk was glued to the colon by a bead of Glutue (WPI).

The whole colon was stretched and then repinned, as described previously (19), to achieve elongation (longitudinal stretch). Mucosal reflexes were evoked by gentle stroking (2–5 strokes) of the mucosa with an artist brush (size 0) (1–3, 18, 36).

The tube was opened into a flat sheet along the mesenteric border to produce mucosa-free preparations. The mucosa was carefully sharp-dissected away. Pins were used to secure one mesenteric border to the base of the organ bath, and tension transducers were attached to the opposite side of the mesenteric border.

Pellet weighing. Pellets were weighed immediately following harvest and also after they were allowed to dry for 48 h.

Electrophysiological recordings. Microelectrodes were advanced into the circular muscle, as previously described (10, 11–13, 36), for electrophysiological recordings.

Histological staining. Cross sections from colonic segments were cut to 5 µm thickness with a cryostat (model CM 3050S, Leica, Wetzlar, Germany) and fixed in 10% (vol/vol) neutral buffered formalin solution. Samples were then embedded in paraffin wax and stained with hematoxylin and eosin solutions.

Immunohistochemistry. After electrophysiological experiments, tissues were removed from the bath and repinned in a Sylgard-lined fixation dish. Tissues were fixed with 4°C paraformaldehyde for 60 min, washed overnight in 0.01 M PBS (pH 7.2), and treated with BSA (1%) for 60 min. Dual staining was performed sequentially: the first primary incubation was carried out for 48 h at 4°C, and tissues were washed in PBS for 4 h at 20°C and then incubated with the second primary antibody. To identify nitricergic enteric neurons, nNOS (NOS1; a gift from P. C. Empson) was used (1). Cyclooxygenase (COX)-2-containing cells were labeled using an antibody against prostaglandin-endoperoxide synthase II (PTGS2, COX II; Cayman Chemical, Ann Arbor, MI). After incubation with primary antibodies, tissues were washed in PBS for 24 h and incubated with secondary antibodies [Alexa Fluor 488 donkey anti-rabbit IgG (H+L), 1:1,000 dilution, and Alexa Fluor 594 donkey anti-sheep IgG (H+L), 1:1,000 dilution; Molecular Probes/Invitrogen], as described elsewhere (25). Whole-mount preparations were viewed and recorded using a confocal scanning microscope (model LSM 510 META, Carl Zeiss Microimaging, Thornwood, NY) with ×10–100 lenses.

Western blots. Total protein was extracted from control, obstructed, and relieved colons. Protein concentration of isolated muscle extracts was determined by the Bradford assay (Bio-Rad, Richmond, CA). A total of 30 µg protein from each lysate was used for the blot. Proteins were subjected to 10% SDS-PAGE and probed with antibodies against IL-6 (Abcam), PTGS2 (COX II; Cayman Chemical), NOS2 (inducible NOS, Transduction Labs), and GAPDH (Santa Cruz Biotechnology). The blot membrane was washed and then incubated with alkaline phosphatase-conjugated anti-rabbit or anti-mouse immunoglobulin G antibody (Santa Cruz Biotechnology). The blot membrane was washed and then incubated with alkaline phosphatase-conjugated anti-rabbit or anti-mouse immunoglobulin G antibody (Santa Cruz Biotechnology). After another wash, the color development was stopped. ImageJ software (National Institutes of Health) was used to calculate the relative densities of protein compared with the housekeeping gene GAPDH. Control experiments were performed in the absence of primary or secondary antibodies.

Intraperitoneal injections of COX-2 inhibitor. Valdecoxib (1 mg/kg) was injected into the abdominal cavity once each day over the 4 days of partial outlet obstruction. Vehicle (saline solution) was injected in controls.

Analysis of Data

Video imaging, tension recordings, and microelectrode recordings were analyzed as described previously (10, 18, 19). Tension was recorded (MP100 acquisition system, Biopac, Santa Barbara, CA) and stored on a personal computer. Frequency, propagation, and amplitude of contractile complexes were measured using AcqKnowledge 3.2.6.

B: length changes in full and empty control (i and ii), acutely obstructed (iii and iv), chronically obstructed (v and vi), and relieved (vii and viii) colons. C: changes in colon length. D: daily fecal pellet output in control and acutely obstructed colons. **P < 0.001. E: hematoxylin-eosin-stained sections of acutely obstructed midproximal region of colon. F: area of longitudinal muscle (LM) and circular muscle (CM) along the length of acutely obstructed colon.
(Biopac Systems, Goleta, CA), and tests for statistical significance were made using SigmaPlot 5.0 (Jandel Scientific, San Rafael, CA). The delay between the 50% amplitude points of CMMCs was calculated to determine propagation velocity. Microelectrode electrophysiology was analyzed using algorithms written in-house, as described previously (10, 12, 18, 19, 37).

Statistical Methods

Statistical comparisons of data were performed using Student’s (paired or unpaired) t-tests or ANOVA, where \( P < 0.05 \) was considered statistically significant; \( n \) refers to the number of animals from which colons were taken. Values are means ± SE.

Drugs and Solutions

Atropine, chremophor, indomethacin, hexamethonium bromide, lidocaine, \( N^\text{-nitro-L-arginine} \), and PGE2 were purchased from Sigma-Aldrich (St. Louis, MO). Valdecoxib was purchased from Tocris (Bristol, UK). Krebs-Ringer bicarbonate solution (in mM: 120.35 NaCl, 5.9 KCl, 15.5 NaHCO3, 1.2 NaH2PO4, 1.2 MgCl2, 2.5 CaCl2, and 11.5 glucose, pH 7.3–7.4) was continuously gassed with 3% CO2-97% O2.

RESULTS

Effect of Manipulation of External Anal Sphincter Diameter

Restriction of the opening diameter of the external anal sphincter with a purse-string suture reduced daily pellet output from 29.7 ± 1.2 to 8.2 ± 1.5 pellets/day (\( n = 15, P = 0.005 \)) by day 4, a reduction of ~73%. At 3–4 days following removal of the suture, average defecation returned to 28.8 ± 2.3 pellets/day (\( n = 8; \text{Fig. 1, A and D} \)).

Fecal pellets in the middle and distal colon of obstructed mice did not properly form; shape, compaction, and desiccation did not occur normally. Fecal pellets were of variable length and often longer in obstructed mice. Wet weight and dry weight of fecal pellets was significantly higher for obstructed than normal mice: 0.03 ± 0.01 g wet wt and 0.01 ± 0.00 g dry wt for normal mice and 0.2 ± 0.03 g wet wt (\( P < 0.001 \)) and 0.05 ± 0.01 g dry wt (\( P < 0.005 \)) for obstructed mice (\( n = 10 \)). Pellets from the obstructed mice were often surrounded by dry powdery fecal matter, which may have prevented water absorption. The pellets crumbled when handled; therefore, dimensional analysis was difficult.

Colonic Elongation and Hypertrophy

As a result of the increase in stool accommodation in the large bowel, colon length markedly increased. In the full state, colon length was 49.7 ± 0.8 mm (\( n = 10 \)), 66.3 ± 1.6 mm (25% increase, \( P < 0.005, n = 10 \)), 70.1 ± 1.9 mm (30% increase, \( P < 0.005, n = 10 \)), and 48.0 ± 1.5 mm (\( n = 10 \)) in control, acutely obstructed, chronically obstructed, and relieved animals, respectively. In the empty state, colon length was 39.6 ± 1.1 mm (\( n = 10 \)), 43.5 ± 2.4 mm (9% increase, \( n = 10 \)), 41.3 ± 1.8 mm (4% increase, \( n = 10 \)), and 41.8 ± 0.7 mm (\( n = 10 \)) in control, acutely obstructed, chronically obstructed, and relieved animals, respectively (Fig. 1C). Hypertrophy of the longitudinal and circular muscle layers was observed along the colon in acutely obstructed mice. The proximal (farthest from obstruction) region appeared to be less affected than regions nearer the obstruction (Fig. 1, E and F; \( n = 5 \)). Furthermore, mast cells and macrophages were not observed in preparations from obstructed mice. Also the mucosa appeared to be unaffected and intact in obstructed mice.

Muscle Tension Recordings From the Full Partially Obstructed Colon

Contractile activity in the isolated, elongated and impacted colons from control mice consisted of CMMCs that often propagated in an oral-to-anal direction (Fig. 2A). In contrast, contractile activity in isolated, elongated and impacted colons from acutely and chronically partially obstructed mice ranged...
from relative quiescence to fairly rhythmic low-amplitude contractions (Fig. 2B). Bath application of N\textsuperscript{-}nitro-L-arginine (100 μM, n = 5) to control (19) and partially obstructed full colons increased amplitude and frequency of contractile activity (Fig. 2, A and B). Subsequent addition of atropine (10 μM) depressed activity (n = 3; Fig. 2, A and B).

Isolated impacted colons were allowed to spontaneously empty their fecal pellets (11, 19). Control full colons emptied (5–7 pellets) in ~30 min (11, 19); in obstructed colons, only one to four pellets emptied within 4.5 ± 0.5 h (n = 4). As each pellet emptied from the impacted colon, it shortened, together with an increase in contractile activity, as observed in control colons (11, 19).

**Fecal Pellet Transit in the Colon**

Epoxy-coated fecal pellets were allowed to spontaneously migrate along isolated segments of colon. Speed of pellet transit was 0.8 ± 0.1, 0.3 ± 0.1, 0.3 ± 0.1, and 0.5 ± 0.1 mm/s in control, acutely obstructed, chronically obstructed, and relieved animals, respectively (n = 6 in each group; Fig. 3).

**Muscle Tension Recordings From the Empty Obstructed Colon**

In empty acutely and chronically obstructed colons, CMMCs did not appear to migrate along the colon, despite the presence of a single fixed epoxy-coated fecal pellet in the center of the colon (18, 19), as measured by three transducers placed along the colon (Fig. 3, B and C); To (proximal colon), Tm (middle colon), and Ta (distal colon). CMMC amplitude in control animals was 24.6 ± 2.3, 18.1 ± 2.7, and 11.4 ± 1.9 mN at To, Tm, and Ta, respectively (Fig. 3A; n = 5). Amplitude was decreased in acutely obstructed animals: 12.3 ± 1.6, 13.0 ± 2.2, and 8.4 ± 1.8 mN at To, Tm, and Ta, respectively (n = 5). Amplitude was also decreased in chronically obstructed an-

---

**Fig. 3.** Pellet propulsion and colonic migrating motor complexes (CMMCs) in an empty obstructed colon. Left: spatiotemporal maps of artificial pellet propagation in control, acutely obstructed, chronically obstructed, and relieved colons. Right: tension recordings from a colon that contained a fixed fecal pellet along points To, Tm, and Ta. Oral-to-anal propagation is less likely in B and C than in A and D.
mals: 12.6 ± 1.3, 11.6 ± 1.5, and 14.2 ± 2.1 mN at To, Tm, and Ta, respectively (n = 5). In relieved animals, amplitude increased to near control measures: 24.5 ± 3.0, 20.6 ± 2.6, and 16.5 ± 5.0 mN at To, Tm, and Ta, respectively (n = 5).

Frequency of CMMC changed from 0.3 ± 0.04 min⁻¹ in control animals (n = 5) to 0.45 ± 0.05, 0.6 ± 0.2, and 0.25 ± 0.05 min⁻¹ in acutely obstructed, chronically obstructed, and relieved animals, respectively (n = 5 in each group; Fig. 3). CMMCs propagated from the oral to the anal direction in 97% of control animals, 32% of acutely obstructed animals, 36% of chronically obstructed animals, and 68% of relieved animals.

Occult Reflexes

A 15% elongation of the colon (19) resulted in a similar depression of CMMCs in isolated colons from control, acutely obstructed, chronically obstructed, and relieved animals throughout the elongation period (n = 4; Fig. 4).

Electrophysiological Recordings of Circular Muscle in the Colon

Resting membrane potential of circular muscle cells was -62 ± 3, −50 ± 6, −53 ± 2 mV, and −58 ± 5 mV in control, acutely obstructed, chronically obstructed, and relieved animals, respectively (n = 5 in each group; Fig. 5, A–C and F). Changes in resting membrane potential can be attributed to the loss of tonic inhibition (13, 34, 37), as observed in changes of inhibitory junction potential (IJP) frequency and amplitude and the unmasking of slow-wave activity in obstructed animals. In control animals, IJP frequency was 15 ± 3 min⁻¹ and amplitude was 9.5 ± 2.6 mV; acutely obstructed

Fig. 4. Occult reflexes in obstructed colon. A–D: tension recordings of occult reflex in response to elongation (15%) in control, acutely obstructed, chronically obstructed, and relieved empty colons.
mice rarely displayed spontaneous IJPs, and amplitude was $1.5 \pm 0.8$ mV; chronically obstructed mice also rarely ($<5$ h$^{-1}$) displayed spontaneous IJPs, and amplitude was $1.3 \pm 0.6$ mV; in relieved animals, frequency was $9 \pm 3$ min$^{-1}$, and amplitude was $8.3 \pm 3.1$ mV ($n = 5$ in each group; Fig. 5E). Excitatory junction potentials and IJPs can still be evoked using electrical field stimulation (EFS; 0.5 ms, 20 V, single pulse, $n = 3$) in acutely and chronically obstructed animals, suggesting that the neuromuscular junction is intact and functional (Fig. 5D). The excitatory junction potential was blocked by atropine (1 μM), and the IJP was blocked by the P2Y receptor antagonist MRS-2500 (1 μM, $n = 3$) (20).

Increases in COX-2 Activity in the Colon

COX-2 (PTGS2)-to-GAPDH ratios increased from 8% (0.08 ± 0.05) in mucosa from control animals to 110% (1.09 ± 0.09) in mucosa from obstructed mice and decreased to 24% (0.24 ± 0.21) in relieved colon.

in mucosa from relieved animals. The muscularis externa, including the myenteric plexus, exhibited a similar pattern of COX-2-to-GAPDH ratio: increases of 3% (0.03 ± 0.02), 402% (4.02 ± 1.27), and 8% (0.08 ± 0.06) in control, obstructed, and relieved animals, respectively (n = 3; Fig. 6, A and B). Immunohistochemical labeling indicated low COX-2 (PTGS2) immunoreactivity in control colon (n = 3; Fig. 6B). In control preparations, there was little COX-2 immunoreactivity within the myenteric plexus (Fig. 6B); however, in the obstructed colon, COX-2 staining was prominent and observed around many myenteric neurons and throughout the ganglia, suggesting that it may also be located in glial cells. COX-2 appeared to colocalize in some nNOS neurons (n = 4; Fig. 6B).

PGE2 (100 nM), a product of the membrane lipid arachidonic acid catalyzed by COX-2, completely abolished spontaneous IJPs and depolarized the circular muscle by 9.0 ± 0.4 mV (n = 4) in control colon (Fig. 6C).

Bath application of valdecoxib (10 μM) for 1–2 h had no significant effect on spontaneous IJPs in control preparations, which were blocked by the 5-HT3 antagonist ondansetron (3 μM, n = 2; Fig. 6D) (12, 18). Valdecoxib (10 μM) also had no significant effect on the amplitude and propagation of CMMCs (data not shown; n = 3). After bath application of valdecoxib (10 μM) for 1–2 h in acutely obstructed (n = 2) and chronically obstructed (n = 3) colons, the resting membrane potential (−55 ± 4 mV), spontaneous IJPs (frequency 12 ± 2.8 min−1), and amplitude of IJPs (8.8 ± 2.5 mV, n = 5) returned toward control levels (n = 5; Fig. 6E). Spontaneous IJPs were also observed in acutely obstructed mice that had received one daily injection of valdecoxib (1 mg/kg ip) throughout the obstruction period (Fig. 6F).

Spontaneous CMMCs in acutely/chronically obstructed colon lacked the preceding inhibition, which was restored following valdecoxib (10 μM; Fig. 7, A and B). Valdecoxib (10 μM, a COX-2 antagonist), which had no detectable effect on control CMMCs (n = 3), increased the rate of pellet propagation to 0.5 ± 0.1 mm/s (n = 6) through the isolated obstructed colon (Fig. 7C). After valdecoxib, the propagation direction, amplitude, and frequency of CMMCs in obstructed mice were similar to those in control mice: 26.7 ± 2.7, 32.9 ± 4.1, and 20.1 ± 1.9 mN at To, Tm, and Ta, and To, respectively; 0.3 ± 0.01 min−1, and 81% (n = 5) (Fig. 7D), presumably because of restored preceding inhibition.
Effect of Mucosa Removal and Mucosal Reflexes in Obstructed Mice

Previously we reported that removal of the mucosa abolishes CMMCs (1, 12, 13). However, when the mucosa was removed from obstructed mice with high COX-2 levels, spontaneous CMMC activity, at a frequency of $0.40 \pm 0.02 \text{ min}^{-1}$, was observed ($n = 6$; Fig. 8A).

In acutely and chronically isolated colons, stroking of the mucosa rarely (1 in ~20 stimuli, $n = 6$) evoked a CMMC (Fig. 8B), as shown for normal colons (1–3, 18). However, after addition of indomethacin (2 $\mu$M), a robust premature CMMC was evoked following mucosal stimulation ($n = 3$; Fig. 8C).

DISCUSSION

Our mouse model of STC induced by partial outlet obstruction requires a simple local procedure and only 15 min for an experienced investigator, as opposed to invasive surgical intervention. Our model shows a number of features that are phenotypically similar to those observed in some humans with STC induced by outlet obstruction; these include reduced fecal output, an impacted elongated colon, slowed transit, and enhanced slow-wave activity resulting from a lack of tonic inhibition, CMMCs, which are still present but do not propagate in an oral-to-anal direction, and muscle hypertrophy.

Many of these changes appear to result from an upregulation of COX-2 activity in the mucosa and muscularis externa, including nNOS-positive myenteric neurons and possibly glia.

Interestingly, muscle hypertrophy along the large intestine of obstructed mice was similar to the gradient in muscle thickness observed in the Hirschsprung’s mouse model, which has an aganglionic constricted rectum resulting from lack of tonic inhibition (35).

The large intestine is always under intrinsic neural activity. Between CMMCs, descending inhibitory nerve pathways exhibit ongoing activity (tonic inhibition); however, during the CMMC, some inhibitory motor neurons reduce their activity, and ascending excitatory nerve pathways are strongly activated (11, 19, 37) (Fig. 9, circuit 1).

Our studies suggest that the motility dysfunction resulting from partial outlet obstruction is due to suppression of the descending (serotonergic) inhibitory nerve pathway (Fig. 9, circuit 2). This nerve pathway is necessary for not only tonic inhibitory drive to the muscle and interstitial cells of Cajal (ICC) in the myenteric region (ICC-MY) between CMMCs, but also for propagating CMMCs (1, 2, 18, 37). Since CMMC activity is observed in obstructed mice, it is clear that the ascending excitatory neural pathways that generate the CMMC are intact (1–3, 12, 13, 37) (Fig. 9, circuit 1). Additionally, ICC-MY, which contact both muscle layers and are activated by excitatory motor neurons during the CMMC, must also be viable, since they are largely responsible for the fast oscillations and slow depolarization phase of the CMMC in the muscle (2, 13) (Fig. 9A). This complex electrical event appears to conduct from ICC-MY into the longitudinal and circular muscle layers to generate muscle action potentials and synchronous contraction of both muscle layers during the CMMC (1, 2, 35). Occult reflexes appear to be normal in the obstructed mice, since colonic elongation still suppresses the CMMC (19); therefore, mechanosensi-
Correlation of the Murine Model With STC in Human Patients

CMMCs in the isolated human colon, which were surgically removed (colectomy) from patients with colon cancer or chronic STC, have a duration and frequency similar to CMMCs in mice (38, 42). CMMCs in the empty isolated colons of cancer patients (controls) can propagate in any direction, similar to those in control mice without a fixed fecal pellet (18). In contrast, colons removed from patients with chronic STC exhibit CMMCs that do not propagate but appear to occur synchronously over long lengths of colon (38, 42), similar to CMMCs in our obstructed mice. Importantly, intraluminal distension of the colon from patients with STC evokes an ascending excitatory neural reflex (premature CMMC) but apparently no descending inhibitory reflex, i.e., anal relaxation, which was observed in control colons (38). It is likely that the lack of propagation of CMMCs in patients with STC is due to the depression of descending inhibitory nerve pathways, similar to our obstructed mice.

Occult Reflexes in Elongated Colons

Our partial outlet obstruction model would predict a powerful suppression of motility by the occult reflex due to increased elongation, reduced mucosal reflexes, and spontaneous CMMCs in mucosa-free preparations.

Contraction along the impacted obstructed colon are of low amplitude because of the release of NO, and emptying is extremely slow compared with that of full control colons. This
suggests that the NO may largely derive from the inhibitory occult reflex pathways (10, 11, 19), which are clearly intact and likely strongly activated because of the increased colonic elongation. Elongated colons are frequently observed in humans with chronic constipation (33, 39). NO is an ideal inhibitory neurotransmitter for the occult reflex, since mechano-sensitive interneurons underlying this neural reflex are always likely to be continuously firing while the colon is elongated. NO is generated by the Ca$^{2+}$-dependent enzyme nNOS in axonal varicosities and, unlike most other inhibitory neurotransmitters stored in vesicles, is unlikely to be depleted following bursts of action potentials that depolarize varicosities causing Ca$^{2+}$ influx (3) (Fig. 9, circuit 3).

Changes in Motility of Partially Obstructed Mice

Increases and decreases in motility have been observed in humans with STC (8). Our obstructed colons appear to be adapting to upregulate motility to expel fecal content against an increased resistance (hypertrophy), since tonic inhibition is absent and slow-wave activity is prominent. As demonstrated in our murine model, acute and chronic obstructions result in a loss of spontaneous IJPs in the circular muscle layer, although IJPs can be readily evoked by EFS, suggesting that the neuromuscular junction is unaffected. Where in the descending inhibitory nerve pathway the depression occurs is unclear. Prostaglandins may inhibit activity in descending serotonergic interneurons or inhibitory (nNOS-positive) motor neurons (2, 10) (Fig. 9). Because this descending inhibitory nerve pathway is depressed, CMMCs do not propagate in an oral-to-anal direction (18, 37) and pellet transit is inhibited in the obstructed colon.

Removal of tonic inhibition cannot be responsible for generating the CMMC, as proposed previously (31), since CMMCs are still present in obstructed mice. They are more likely generated primarily by the activation of ascending excitatory nerve pathways, which activate excitatory motor neurons that release ACH and tachykinins onto pacemaker ICC and the muscle (1, 2, 6, 13, 37) (Fig. 9, circuit 1).

COX-2 in Partially Obstructed Mice

Typically, colitis and diarrhea are associated with increases in COX-2, which is found in enteric neuronal cell populations (23–25). Increases in COX-2, but decreases in COX-1, occur in patients with chronic STC (7). We found that COX-2 inhibitors restored IJP activity, suggesting that the descending inhibitory nerve pathway was only suppressed by prostaglandins. PGE$_2$ was found to block spontaneous IJPs and depolarize the circular muscle, suggesting that it was removing tonic inhibition. COX-2 and nNOS were colocalized to a small population of nNOS neurons; similar results have been shown in gastric nNOS neurons, suggesting that COX-2 can be constitutively expressed in some guinea pig myenteric neurons and human colonic tissue (16, 25). Additionally, prostaglandins such as PGE$_2$ have been shown to regulate myenteric neuron activity during inflammation (23, 24).

CMMCs Without the Mucosa and Mucosal Reflexes

The role of the mucosa in generating CMMCs is controversial (22, 31). We have observed that administration of ondansetron (a 5-HT$_3$ antagonist) or removal of the mucosa abolishes spontane-
