Submitted 24 March 2015; accepted in final form 1 December 2015

OBESITY HAS BECOME A MAJOR health issue in recent decades, and estimates indicate that more than two-thirds of adults in the United States are either overweight or obese (27). Obesity leads to a substantially higher risk of developing features of the metabolic syndrome such as hypertension; dyslipidemia; type 2 diabetes; coronary heart disease; nonalcoholic fatty liver disease (NAFLD); and endometrial, breast, prostate, and colon cancer (25, 31).

Obesity is associated with chronic, low-grade white adipose tissue inflammation in response to metabolic stimuli (24). Adipose tissue macrophages secrete proinflammatory cytokines and chemokines such as tumor necrosis factor-α (TNF-α), interleukin (IL)-6, IL-1β, and monocyte chemotactic protein-1 (MCP-1 or Ccl2) (12, 28). Elevated levels of TNF-α, IL-1β, and IL-6 are associated with insulin resistance and diabetes, and neutralization of TNF-α improves insulin sensitivity in obese rodents (18, 19, 37).

It is known that the gut microbiota also contributes to metabolic disease. Toll-like receptor-5 (TLR5)-deficient mice develop hallmark features of the metabolic syndrome such as hyperlipidemia, hypertension, insulin resistance, and weight gain (12, 40). In the gastrointestinal tract, TLR5 is activated by bacterial products such as flagellin, which induces the production of IL-1β, IL-6, IL-12, IL-18, and IL-23 in dendritic cells (30). These cytokines lead to the production of IL-22 from Th17, Th1, innate lymphoid, natural killer cells, and γδ T cells (30). IL-22 is involved in the production of the antimicrobial peptides known as regenering islet-derived (Reg)-3 beta and gamma (Reg3b and Reg3g, respectively) in Paneth cells; furthermore, IL-22 induces goblet cells to produce mucins (30). It was recently discovered that the metabolically beneficial cytokine IL-22 is impaired in obese mice (42). Administration of IL-22 to obese mice improves insulin sensitivity, decreases chronic inflammation, and modulates lipid metabolism in liver and adipose tissue (42). Therefore, IL-22 is not only crucial for maintaining the mucosal barrier function and mediating innate immunity, but it also has important metabolic functions (30). Fatty liver disease depends on intestinal microbiota as well (35). Administration of IL-22 protects from various liver diseases (20, 32, 46).

The intestinal mucus layer as a physical barrier protects the epithelium against noxious agents, viruses, and pathogenic bacteria (15). Goblet cells secrete the gel-forming mucins 2, 5AC, and 6 (Muc2, Muc5AC, and Muc6, respectively) in the gastrointestinal tract. These mucins contribute to the viscous properties of the intestinal mucus layer (23). Muc2 deficiency in mice is associated with disruption of epithelial homeostasis and the development of colon cancer (39). On the other hand, Muc2-knockout mice fed alcohol are protected from bacterial overgrowth due to increased killing of commensal bacteria, and they exhibit reduced endotoxemia and liver injury (15). So far it has been reported that obesity and NAFLD are characterized by altered gut microbiota (1, 16, 35, 38), inflammation (29, 35), and gut barrier disruption (3, 4, 9, 35). However, to our knowledge, no patient data or experimental studies exist that have assessed the function of the intestinal mucus layer in obesity and NAFLD. We studied the role of Muc2 as the major component of the intestinal mucus layer using a high-fat diet (HFD) feeding model to induce obesity and obesity-related liver disease in Muc2-knockout and wild-type (WT) mice.
MATERIALS AND METHODS

Mice. Muc2-deficient mice (back-crossed to C57BL/6J mice for more than 10 generations) were kindly provided by Dr. Anna Velcich (Albert Einstein College of Medicine, Yeshiva University, New York, NY) (15, 39). Heterozygous mice were bred to obtain WT and knockout littermate mice. Three nonlittermate knockout mice that ate regular chow were added to the control group for hepatic triglyceride measurement, real-time quantitative polymerase chain reactions (qPCRs) procedures, and IL-22 ELISA. Animals were maintained in a temperature-controlled room (22°C) on a 12:12-h light-dark cycle. Age-matched male and female mice were used for this study (as indicated in the figure legends) and were fed HFD (59% energy by fat; Bio-Serv, Frenchtown, NJ) or regular chow diet (13% energy by fat; 1816971-206; LabDiet, Brentwood, MO) for 16 wk. The caloric profile of the HFD consisted of 3.24 kcal/g from fat (lard), 1.43 kcal/g from carbohydrates (maltodextrin, sucrose), and 0.82 kcal/g from proteins (casein) (total 5.49 kcal/g), whereas the control diet contained 0.45 kcal/g from fat, 2.12 kcal/g from carbohydrates, and 0.84 kcal/g from proteins (total 3.41 kcal/g). It is this regular lar-derived HFD that is referred to throughout this manuscript unless HFD with another qualifier is specifically mentioned. For the plant-derived HFD experiments, age-matched male mice were used and fed HFD (41.5% energy by fat; S3282; TestDiet, St. Louis, MO) for 14 wk. The caloric profile of the plant-derived HFD consisted of 1.80 kcal/g from fat (corn oil, hydrogenated coconut oil, cholesterol), 1.837 kcal/g from carbohydrates (sucrose, maltodextrin, corn starch, powdered cellulose), and 0.695 kcal/g from proteins (soy protein concentrate) (total 4.33 kcal/g). For intestinal decontamination, age-matched male mice were fed the lar-derived HFD for 21 wk. During the last 5 wk they were gavaged with 4 mg/kg vancomycin, 8 mg/kg ampicillin, 8 mg/kg neomycin, 8 mg/kg metronidazole, and 0.69 g/kg gentamicin. The gavage was carried out twice daily 5 days/wk and once daily 2 days/wk. Mice had ad libitum access to water. Food intake was quantified in week 3 and week 12. This was carried out by forming a solid round lump of HFD and weighing it on the first day of the week and then 7 days later; the difference was the absolute food intake. Similarly, the mouse body weight was determined on the first day of the week and then 7 days later. The daily food intake in gram per gram of body weight was then calculated by dividing the absolute food intake per day by the averaged mouse weight. Body weight was measured once a week for the duration of the respective experiment. All animals studies were reviewed and approved by the Institutional Animal Care and Use Committee of the University of California, San Diego.

Administration of flagellin. Blood was taken from male HFD-fed WT and Muc2<sup>-/-</sup> mice to determine IL-22 plasma levels at baseline. After 7 days, 200 μl of mouse tissue using TRIZol (Invitrogen, Carlsbad, CA). RNA was digested with DNase using the DNA-free DNA removal kit (Ambion, Carlsbad, CA) and reverse transcribed using the High Capacity cDNA Reverse Transcription kit (Applied Biosystems, Foster City, CA). Gene expression was detected with Universal SYBR Green Supermix (Bio-Rad, Hercules, CA) as described (36, 41) using primer sets specific for IL-1β, TNF-α, Ccl2, F4/80, ACOX1, HSL, ATG, IL-22, Reg3b, Reg3g, HMGC2, TBP, and 18S genes (all from the National Institutes of Health qPrimerDepot). The relative expression of the target genes was obtained by using a standard curve and normalized to TBP as an internal control in adipose tissue, and 18S as an internal control in all nonadipose tissues. To quantify intestinal bacteria, DNA was extracted from adherent and luminal intestinal contents as described (15). DNA was amplified using published 16S rRNA primer sets for universal bacteria (17) and SYBR Green. To determine the total bacterial load present in the cecum, the qPCR value for each sample was multiplied by the total amount of DNA per gram of cecal content. Firmicutes, Bacteroidetes, 

Protein expression analysis. Immunoblot analysis was performed as described (15) using anti-UCP1 (Abcam) and anti-β-actin (Sigma-Aldrich) or anti-HSP90 (Cell Signaling) antibodies as loading controls. Densitometry of immunoblot analysis was performed using ImageJ software (National Institutes of Health, Bethesda, MD).

Plasma assays. IL-22 in mouse plasma was measured using an ELISA Development Kit (R&D Systems, Minneapolis, MN) according to the manufacturer’s instructions. All material used for harvesting blood and measuring endotoxin was pyrogen free. The LPS level in the plasma was determined by employing an ELISA Kit (CloudClone, Houston, TX) according to the manufacturer’s protocol.

Statistical analysis. The unpaired Student’s t-test was used for statistical analysis (Prism, GraphPad Software, La Jolla, CA). Results are presented as means ± SE. A value of P < 0.05 was selected as the level of significance.
Fig. 1. Mucin-2 (Muc2)-deficient mice gain less body weight than wild-type (WT) mice after 16 wk of being fed a high-fat diet (HFD). WT and Muc2-/- mice were fed regular chow (n = 2–4) or HFD (n = 6–8) for 16 wk. A: body weights in grams (top) and % relative to starting weight (bottom). B: representative mice after 16 wk of HFD. C: subcutaneous fat weight (left), epididymal fat weight (middle), brown adipose tissue weight (right) with representative photographs. D: daily food intake during week 3 and week 12 on HFD. E: fecal triglyceride, protein, monosaccharide, and total carbohydrate concentration in groups of mice fed HFD. *P < 0.05.
RESULTS

Muc2-deficient mice fed HFD showed significantly less body weight gain than their WT counterparts. Feeding mice HFD for 16 wk is an established model for diet-induced obesity, which is accompanied by hepatic steatosis and insulin resistance (10). After 16 wk eating HFD, WT mice exhibited a significantly higher body weight compared with Muc2-deficient mice (Fig. 1, A and B). Similarly, the latter displayed significantly decreased weights of subcutaneous and epididymal white adipose tissue and brown adipose tissue relative to WT mice also given HFD (Fig. 1C); we also noticed a whitening of the brown adipose tissue in WT mice fed the HFD (Fig. 1C). These differences cannot be explained by a different amount of HFD ingested by these mouse strains, because food intake was comparable between the groups as exemplified by the quantity of HFD consumed in week 3 and week 12 of the experiment (Fig. 1D). We next examined whether the absence of a mucus layer would affect intestinal absorption of fat, proteins, or carbohydrates. WT and Muc2-deficient mice showed similar concentrations of triglycerides, proteins, and simple and total carbohydrates in the feces (Fig. 1E). Thus Muc2-deficient mice are protected from diet-induced obesity, which could not be explained by differences in food intake or malabsorption of fat, proteins, or carbohydrates.

Muc2 deficiency results in improved glucose homeostasis following HFD. The intraperitoneal GTT demonstrated that Muc2−/− mice exhibited significantly lower glucose blood levels and hence improved glucose tolerance after HFD relative to WT mice (Fig. 2A). Consistent with this, mice lacking Muc2 revealed a greater responsiveness to insulin than WT mice fed HFD, as shown by the intraperitoneal ITT (Fig. 2B). Hence the better glycemic control further demonstrates that Muc2 deficiency results in improved features of the metabolic syndrome. There is at least one published report of sex-specific differences in glucose tolerance and insulin responsiveness after HFD (11). Female Muc2-deficient mice fed a lard-derived HFD were not protected from obesity and they showed the same glucose tolerance and insulin sensitivity as female WT mice fed a lard-derived HFD (Fig. 3, A and B). However, loss of protection from features of the metabolic syndrome could be due to a significantly higher food intake in female Muc2−/− mice during the entire feeding period (Fig. 3C).

Hepatic steatosis is significantly ameliorated in Muc2−/− mice following HFD. Because fatty liver disease is part of the metabolic syndrome and is linked to the onset of insulin resistance, we next investigated hepatic steatosis. Livers showed a trend toward lower weight in Muc2−/− mice following a 16-wk HFD, but this was not significantly different (Fig. 4A). Livers of WT mice appeared more steatotic than livers from Muc2−/− mice following HFD, as evidenced macroscopically by a different color and texture (Fig. 4A). This was confirmed on liver sections stained with hematoxylin and eosin (Fig. 4B) and oil red O (Fig. 4C), as WT mice showed impressively more and larger fat droplets than Muc2−/− mice following 16 wk of HFD. Finally, hepatic levels of triglycerides were significantly reduced in mice deficient in Muc2 and fed HFD (Fig. 4D). Thus Muc2 deficiency largely prevents the development of a fatty liver following HFD.

White adipose tissue showed less inflammation and an up-regulated expression of genes involved in lipolysis and fatty acid β-oxidation in Muc2-deficient mice fed HFD. Inflammation in adipose tissue has been described as a driver for the development of obesity-associated liver disease and insulin resistance in humans (2, 18) and animals (19, 45). As stated earlier, white adipose tissue was significantly more prominent in WT mice than in Muc2−/− mice (Fig. 1C). Markers of inflammation such as IL-1β, TNF-α, Ccl2 (MCP-1), and F4/80 were elevated in white adipose tissue in WT mice fed HFD relative to WT mice fed regular chow; but most importantly, they were significantly higher in WT mice that were fed HFD than in their Muc2-deficient littersmates (Fig. 5A).

The key lipolysis enzymes adipose triglyceride lipase (ATGL, or PNPLA2) and hormone-sensitive lipase (HSL, or LIPE) were expressed more highly in white adipose tissue in Muc2−/− mice fed HFD than in WT mice (Fig. 5B). Similarly, fatty acid β-oxidation was increased in Muc2−/− mice relative to WT mice fed HFD, as exemplified by the increased gene expression of palmitoyl acyl-CoA oxidase 1 (ACOX1) (Fig. 5C). More lipolysis provides more free fatty acids for β-oxidation in adipose tissue.

Because there was a more pronounced increase in body weight in HFD-fed WT mice compared with Muc2−/− mice in spite of a similar food intake and similar fecal contents, we sought other explanations that would account for the ingested calories not stored in the form of fat tissue in Muc2−/− mice. The level of physical activity was similar between HFD-fed WT and Muc2−/− mice (Fig. 5D). Since ketone synthesis in

Figure 2. Muc2−/− mice fed HFD show a better glucose tolerance and insulin sensitivity than WT mice fed HFD. WT and Muc2−/− mice were fed regular chow (n = 3–4) or HFD (n = 8) for 16 wk. A: glucose tolerance test (GTT). B: insulin tolerance test (ITT). *P < 0.05 between WT mice and Muc2−/− mice both fed HFD.
the liver is inhibited by insulin, and obese subjects show relative insulin deficiency and augmented levels of ketone bodies in the blood (14), we assessed hepatic genes involved in ketone synthesis. HFD-fed WT mice had an induced expression of genes involved in ketone body synthesis in the liver relative to chow-fed WT mice; and Muc2-deficient mice exhibited a significantly lower level of these genes than WT mice after HFD (Fig. 5E). Furthermore, the activity of uncoupling protein-1 (UCP1) in the mitochondria in mostly brown adipose tissue leads to dissipation of chemical energy as heat instead of conserving it in adenosine triphosphate (ATP) (34). The protein expression of UCP1 was higher in brown adipose tissue of Muc2-knockout mice than WT mice after 16 wk of HFD (Fig. 5F and G). This could account for increased energy expenditure in HFD-fed Muc2-deficient mice. Because UCP1 activity is suppressed by inflammation (34), we then checked the level of inflammation in brown fat. The inflammatory markers TNF-α and Ccl2 were reduced in brown adipose tissue in Muc2-deficient mice compared with WT mice after 16 wk of HFD (Fig. 5H). Hence, the higher protein expression of UCP1 in Muc2−/− mice fed HFD might be due to the lower level of inflammation in the brown adipose tissue.

Taken together, these inflammatory and metabolic differences in white and brown adipose tissue could explain the different phenotype in features of the metabolic syndrome. Muc2 deficiency leads to higher intestinal and systemic levels of IL-22 following HFD. We have shown that Muc2−/− mice display elevated levels of the antimicrobials Reg3b and Reg3g in the intestine (15). IL-22 exerts an essential role in regulating the intestinal antimicrobial barrier (30, 42), inducing Reg3b, Reg3g, and mucins (30). Moreover, IL-22 directly increases expression of the lipolysis/β-oxidation genes HSL, ATGL, and ACOX1, and improves insulin sensitivity (42). IL-22 also dampens chronic inflammation in fat tissue (42), and an IL-22 receptor is also found in brown adipose tissue (43). We therefore investigated the role of IL-22 in our HFD model. IL-22 gene expression was suppressed in the small intestine of HFD-fed WT mice compared with WT mice fed regular chow (Fig. 6A), consistent with recently published data (42). Small intestinal IL-22 mRNA levels were significantly
Fig. 4. HFD results in a fatty liver in WT mice, but not in Muc2\(^{-/-}\) mice. WT and Muc2\(^{-/-}\) mice were fed regular chow (\(n = 2-5\)) or HFD (\(n = 8\)) for 16 wk. A: liver weights and representative photographs of fatty liver from mice in groups fed the HFD. B: representative liver sections after hematoxylin and eosin staining, \(\times 40\) magnification. C: photographs of representative liver sections after oil red O staining, \(\times 100\) magnification. D: hepatic triglyceride levels. *\(P < 0.05\).
higher in Muc2-knockout mice fed HFD relative to WT mice fed HFD (Fig. 6A). Similarly, IL-22 target genes Reg3b and Reg3g were elevated in the small intestine of HFD-fed Muc2-deficient mice compared with WT mice (Fig. 6B). Muc2-knockout mice that ate the HFD demonstrated overall higher levels of inflammatory gene expression in the small (Fig. 6C) and large (Fig. 6E) intestines than HFD-fed WT mice. HFD-fed Muc2<sup>−/−</sup> mice showed signs of early inflammation as evidenced by a more pronounced submucosal edema (Fig. 6D, straight line) and inflammatory infiltrates composed primarily of neutrophils (Fig. 6D, arrow) in the ileum. Colon samples from HFD-fed Muc2<sup>−/−</sup> mice demonstrated similar early signs of inflammation, but to a lesser degree (Fig. 6F). However, increased intestinal inflammation did not result in clinical signs of diarrhea or rectal bleeding (15), and is therefore best described as subclinical intestinal inflammation.

To investigate whether increased intestinal IL-22 gene expression directly translates into higher IL-22 protein expression and secretion, plasma IL-22 levels were determined. Supporting our intestinal results, HFD-fed Muc2<sup>−/−</sup> mice showed significantly higher IL-22 plasma levels than HFD-fed WT mice (Fig. 6G). Thus increased systemic IL-22 plasma levels appear to offer an explanation for the protection of Muc2-deficient mice against features of the metabolic syndrome.

To further elucidate whether systemic hyperresponsiveness contributes to higher IL-22 plasma levels in Muc2<sup>−/−</sup> mice, we tested this possibility by administering flagellin via intraperitoneal injection. This route of delivery bypasses the gastrointestinal tract and, in particular the intestinal mucus layer, and flagellin is absorbed directly into the systemic circulation. Flagellin is a TLR5 agonist and induces IL-22 plasma levels (42). Intraperitoneal injection of flagellin resulted in higher IL-22 plasma levels in both HFD-fed WT and Muc2<sup>−/−</sup> mice. The significant difference in IL-22 plasma levels at baseline between the groups disappeared (Fig. 6H). These results suggest that the absence of the mucus layer has an important effect on the production of intestinal IL-22.

Furthermore, intestinal dysbiosis is associated with obesity and obesity-related liver disease (3, 35, 38). Correspondingly, in our experiments administration of HFD resulted in intestinal bacterial overgrowth in WT and Muc2<sup>−/−</sup> mice (Fig. 7A). Muc2<sup>−/−</sup> mice fed HFD displayed significantly higher Bacteroidetes and a trend toward a lower Firmicutes:Bacteroidetes ratio compared with WT mice; no difference in Akkermansia nor Lactobacillus was observed between these groups (Fig. 7, B and C). No difference in plasma LPS was detected between WT and Muc2-deficient mice after being fed HFD (Fig. 7D). To determine whether the phenotype of the Muc2-deficient mice depends on host-microbiome interactions, mice were fed HFD for 16 wk and then treated with antibiotics for 5 wk. WT mice fed HFD showed no significant changes in body weight (Fig. 7E), but similarly to published data (3), they exhibited significant improvements in glucose tolerance and insulin responsiveness (Fig. 7F) after an intervention therapy with antibiotics relative to their pretreatment state. Antibiotic treatment did not change body weight, glucose tolerance, or insulin responsiveness in Muc2<sup>−/−</sup> mice compared with their pretreatment state; their values in the GTT and ITT were also not significantly different from those of WT mice after antibiotics were administered (Fig. 7, E and F). IL-22 gene expression in the ileum was not different after antibiotic intervention in WT and Muc2-deficient mice fed HFD (Fig. 7G). Thus, although antibiotic treatment results in a reduced inflammation with favorable effects on metabolic functions in WT mice fed HFD (3), the beneficial immunomodulator IL-22 was no longer elevated in the ileum of Muc2<sup>−/−</sup> mice, which could explain the vanishing metabolic advantage in the knockout mice and the similar phenotype in both WT and Muc2<sup>−/−</sup> mice given HFD and antibiotics.

It has been reported that different HFD preparations lead to different intestinal inflammatory responses in Muc2<sup>−/−</sup> mice (22). Interestingly, male Muc2-deficient mice fed a plant-derived HFD showed a similar body weight gain, glucose tolerance, and insulin sensitivity compared with WT mice fed a plant-derived diet for 16 wk, with a similar food intake (Fig. 8, A–C). Intestinal IL-22 levels in Muc2<sup>−/−</sup> mice were not significantly different from those of WT mice fed a plant-derived HFD (Fig. 8D). Thus the protection of Muc2-deficient mice from diet-induced obesity and metabolic syndrome is largely dependent on the source of the dietary fat.

**DISCUSSION**

In this study we investigated the role of Muc2 in obesity and NASH in a preclinical model. Muc2-deficient mice fed HFD were protected from diet-induced weight gain, fatty liver, and insulin resistance. Additionally, they displayed less inflammation, upregulated lipolysis and β-oxidation in white adipose tissue, and increased expression of UCP1 involved in thermogenesis in brown adipose tissue after 16 wk of being fed HFD. Protection from features of the metabolic syndrome could not be explained by changes in food intake in male Muc2-deficient mice. Mice lacking Muc2 that ate HFD displayed higher intestinal and plasma levels of IL-22 and higher levels of the intestinal antimicrobials Reg3b and Reg3g in relation to WT mice fed the same diet. Increased systemic levels of IL-22 provide an explanation for the resistance against diet-induced features of the metabolic syndrome in the absence of an intestinal mucus layer.

**Fig. 5.** Gene expression in white and brown adipose tissue, and energy expenditure in WT and Muc2<sup>−/−</sup> mice after 16 wk of HFD. WT or Muc2<sup>−/−</sup> mice were fed regular chow (n = 3–5) or HFD (n = 7–8) for 16 wk. A–C: gene expression by quantitative polymerase chain reaction (qPCR) in epididymal fat. A: inflammatory markers IL-1β, TNF-α, monocyte chemotactic protein-1 (MCP-1 or Ccl2), and F4/80. B: lipolysis enzymes adipose triglyceride lipase (ATGL) and hormone-sensitive lipase (HSL). C: fatty acid β-oxidation enzyme palmitoyl acyl-CoA oxidase 1 (ACOX1). D and E: WT and Muc2<sup>−/−</sup> mice were fed regular chow (n = 2–4) or HFD (n = 3–8) for 16 wk. D: level of physical activity. E: hepatic gene expression by qPCR, 3-hydroxy-3-methylglutaryl-CoA lyase (or HMG-CoA lyase, HMGCL) and the rate-limiting enzyme of ketogenesis, mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase 2 (HMGCSS2). F: immunoblot for uncoupling protein-1 (UCP1) in brown adipose tissue. G: densitometry of immunoblot images of UCP1 was performed with β-actin as loading control in brown adipose tissue of four separate immunoblot membranes (n = 5–6 for regular chow-fed mice and n = 11 for HFD-fed mice). H: TNF-α and MCP-1 (Ccl2) gene expression in brown adipose tissue (n = 4–5 for regular chow-fed mice and n = 6–8 for HFD-fed mice). *P < 0.05.
Our results suggest that IL-22 produced and secreted by immune cells in the intestine is the driving force behind increased systemic IL-22 levels. Following intraperitoneal injection of flagellin, differences in IL-22 plasma levels between HFD-fed WT and Muc2\(^{-/-}\) mice vanished. This suggests that the absence of the intestinal mucus layer does not lead to a generalized activation of the immune system, but the activation might be restricted to the mucosal immune system.
How can the absence of a protective barrier be beneficial for the host? The host deploys several barriers to protect the body from invading intestinal microbes and their products. Epithelial cells with their tight junctions and the mucus layer that covers the surface of intestinal epithelial cells are examples for physical barriers (35). Because Muc2 is the major secreted mucin in the intestinal tract, its absence dramatically decreases the overall mucus layer (15). If there is a breach in this mechanical...
Fig. 7. HFD leads to intestinal bacterial overgrowth, bacterial translocation, and antibiotic treatment of WT mice fed HFD results in an improved glucose tolerance and insulin sensitivity. A–D: WT and Muc2−/− mice were fed regular chow (n = 4–5) or HFD (n = 5–8) for 16 wk. A: total intestinal bacteria in cecum. G: gene expression by qPCR of IL-22 in ileum. *P < 0.05.
barrier, as it occurs in Muc2-deficient mice, it is likely that microbial products have better access to immune cells located in the lamina propria. This could lead to the activation of immune cells such as monocytes, macrophages, and dendritic cells as a first-line, innate immune defense. Such activation primarily aims at restoration of the barrier dysfunction and initiation of a wound-healing process. Several proinflammatory mediators such as TNF-α and Ccl5 have been described to be involved. These molecules activate intracellular signaling cascades in epithelial cells that result in disruption of the tight junctions and cause further progression of disease (5, 8, 16). Components in the intestinal inflammation process such as the secretion of IL-22 are also beneficial. IL-22 is very effective at inducing antimicrobial molecules such as Reg3b, Reg3g, and mucin production (30, 42). IL-22 effectively protects from experimental colitis (48). An intestinal immune response that is characterized by predominately protective mediators will be beneficial for the host and will restore intestinal homeostasis. In Muc2 deficiency, there seems to be a very strong IL-22 response and an upregulation of IL-22 target genes following consumption of a lard-derived HFD. Currently, we can only speculate about why the absence of a mucus layer provokes this rather beneficial effect. Intestinal inflammation could be driven by dysbiosis and released products or metabolites from the dysbiotic microbiota (16). Muc2 deficiency and its associated leakiness might lead to more translocation of microbial mediators to the lamina propria that activate IL-22 expression. However, antibiotic treatment alone was not sufficient to reduce features of the metabolic syndrome in Muc2-deficient mice. It is therefore unlikely that dysbiosis alone is enhancing the mucosa-protective response in the absence of a mucin layer. Interestingly, the protective effect is lost once the source
of fat is changed from animal- to plant-derived. It is therefore conceivable that food-derived metabolites drive the strong mucosal IL-22 response in the absence of mucin, which eventually will increase systemic IL-22 plasma levels. In our experiments, the plant-derived HFD had 6% fiber content, and the lard-derived HFD contained no fiber at all. Taking into account the anti-inflammatory properties of fiber (21), this could be one factor that explains the phenotype difference after Muc2−/− mice were fed a plant-derived HFD. However, the absence of the mucus layer is not beneficial in every instance. For example, intestinal pathogens such as Salmonella can penetrate and invade the host more easily (47).

IL-22 is not only good for restoring intestinal homeostasis, but it also exerts beneficial effects on a broad range of liver diseases (20, 32, 46) and the metabolic syndrome (42). A lard-derived HFD suppresses intestinal and systemic IL-22 in mice (42), which is in agreement with our results. Most interestingly, therapeutic administration of IL-22 has recently been shown to prevent and treat the metabolic syndrome in mice (42). The detailed mechanism of how IL-22 protects from diet-induced obesity is not entirely known (44). It involves suppression of inflammation, induction of lipolysis and β-oxidation in white adipose tissue (42), which we have also observed in our model. Thus increased systemic IL-22 is the mostly likely explanation why Muc2-deficient mice are protected from the metabolic syndrome. However, we cannot rule out that other mediators that might be induced in response to the intestinal barrier failure might contribute to the protection as well.

In summary, we describe a genetic model of mucin deficiency that prevents metabolic syndrome development. A strong intestinal immune response is initiated as a consequence of an intestinal barrier dysfunction. Increased levels of systemic IL-22 protect mice from diet-induced obesity and its consequences. Future studies need to determine the link between Muc2 deficiency and initiation of this beneficial restoration process in the intestinal lamina propria. Determining which metabolites cause this immune response could have tremendous clinical implications because such interventions hold promise to serve as a treatment option for patients suffering from the metabolic syndrome.

Role of Mucin-2 in Fatty Liver Disease and Obesity
